ABSTRACT

Although concurrent data structures are commonly used in practice on shared-memory machines, even the most efficient concurrent structures often lack performance theorems guaranteeing linear speedup for the enclosing parallel program. Moreover, efficient concurrent data structures are difficult to design. In contrast, parallel batched data structures do provide provable performance guarantees, since processing a batch in parallel is easier than dealing with the arbitrary asynchrony of concurrent accesses. They can limit programmability, however, since restructuring a parallel program to use batched data structure instead of a concurrent data structure can often be difficult or even infeasible.

This paper presents BATCHER, a scheduler that achieves the best of both worlds through the idea of implicit batching, and a corresponding general performance theorem. BATCHER takes as input (1) a dynamically multithreaded program that makes arbitrary parallel accesses to an abstract data type, and (2) an implementation of the abstract data type as a batched data structure that need not cope with concurrent accesses. BATCHER extends a randomized work-stealing scheduler and guarantees provably good performance to parallel algorithms that use these data structures. In particular, suppose a parallel algorithm has \( T_1 \) work, \( T_w \) span, and \( n \) data-structure operations. Let \( W(n) \) be the total work of data-structure operations and let \( s(n) \) be the span of a size-P batch. Then BATCHER executes the program in \( O((T_1 + W(n) + ns(n))/P + s(n)T_w) \) expected time on \( P \) processors. For higher-cost data structures like search trees and large enough \( n \), this bound becomes \( (T_1 + n\log n)/P + T_w\log n) \), provably matching the work of a sequential search tree but with nearly linear speedup, even though the data structure is accessed concurrently. The BATCHER runtime bound also readily extends to data structures with amortized bounds.

Keywords

Data structures, work stealing, scheduler, batched data structure, implicit batching

1. INTRODUCTION

A common approach when using data structures within parallel programs is to employ concurrent data structures — data structures that can cope with multiple simultaneous accesses. Not only is it challenging to design and analyze concurrent data structures, but the existing performance theorems do not often imply linear speedup for the enclosing program. The straightforward way to analyze a program that uses a concurrent data structure is to assume the worst-case latency for each access. For a limited set of concurrent data structures (see Section 6), the worst-case latency is low enough that this approach is effective. In more general cases, the worst-case latency is often linear in the number of processors in the system (or worse), e.g., for Braginsky and Petrank’s lock-free B+ -tree [7]. If \( n \) data-structure accesses each keep a processor busy for \( \Omega(P) \) timesteps, then the running time on \( P \) processors is at least \( \Omega(nP/P) = \Omega(n) \). An \( \Omega(n) \) bound means that accesses are essentially sequential — there is no significant speedup guarantee when running on \( P \) processors.

Concurrent data structures are in some sense overkill for use within a single parallel program because they are designed to cope with difficult access patterns. Since the data-structure accesses belong to the same enclosing program, they can, in principle, coordinate with each other. A key idea behind our work is to leverage a runtime scheduler and to handle this coordination.

The primary goal of this paper is to 1) describe a good scheduler for executing a broad class of parallel programs that make parallel
accesses to data structures, and 2) provide a corresponding general performance theorem for this scheduler. Our performance theorem exhibits an attractive modularity: the data structure may be analyzed in isolation of the program that uses it, and the parallel program may be analyzed without considering the specific implementation of the data structure. This modularity makes the theorem easy to apply while still achieving provably good speedup, e.g., for \( n \) parallel accesses to a search tree with large enough \( n \), our scheduling theorem proves a completion time of \( \Theta(n \log n/P) \), which is asymptotically optimal and has linear speedup. We are unaware of any comparable aggregate bounds for concurrent search trees.

**Runtime scheduling.** This paper focuses on parallel programs expressed through dynamic multithreading\(^2\) (see [11, Ch. 27]), which is common in many parallel languages and libraries, such as Cilk dialects [18, 26], Intel TBB [35], Microsoft Task Parallel Library [39] and subsets of OpenMP [30]. The programmer expresses algorithmic parallelism, through linguistic constructs such as “spawn” and “sync,” “fork” and “join,” or parallel loops. The programmer does not provide any mapping from subcomputations to processors. The program is typically scheduled using an efficient work-stealing scheduler (e.g., [6]) provided by the runtime system. A parallel program (without parallel data structure accesses) having \( T_1 \, \text{work} \) — the running time on 1 processor, and \( T_w \, \text{span} \) — the length of the critical path, can be executed in \( O(T_1/P + T_w) \) (expected) time on \( P \) processors (or workers) using a work-stealing scheduler. This running time is asymptotically optimal and guarantees linear speedup to programs with sufficient parallelism.

This paper generalizes the above result by describing a scheduler and corresponding performance theorem for dynamic multithreaded programs that make parallel accesses to a data structure. This performance theorem implies that parallel programs (with sufficient parallelism) using efficient data-structure implementations can execute with linear speedup, even if the program’s work is dominated by data-structure accesses.

**Batched data structures.** One way to programmatically coordinate data-structure accesses is to use only batched data structures, where the program invokes an entire set of data-structure operations synchronously, and the batched data structure performs these operations collectively in parallel. The main advantages of batched data structures are: (1) only one batch is active at a time, obviating the need for complicated concurrency control within the data structure, (2) parallelism may be used to accelerate individual batches, and (3) they are relatively easy to analyze; if a program generates a sequence of batches, we can simply add the running time of this sequence of batches to the running time of the program. For example, (batched) parallel priority queues [8, 12, 13, 36] have been utilized to prove efficient running time on parallel algorithms such as shortest paths and minimum spanning tree [8, 13, 32].

Getting provably good performance by replacing a concurrent data structure with a batched data structure can require drastic code restructuring, however, since the parallel program must explicitly group accesses into batches. In some cases, such a restructuring may not even be possible. For example, an on-the-fly race detector [29, 5, 34] updates a series-parallel-maintenance data structure on forks and joins while executing an input program. In this application, the data structure must be updated before the program flow continues past the calling point, so it seems impossible to reorganize the operations into batches by restructuring the algorithm.

\(^2\)Dynamic multithreading is also sometimes called “fork-join” parallelism.

**Contributions**

This paper shows we can achieve a modular analytic abstraction whereby the data structure \( \mathcal{D} \) and the enclosing program \( \mathcal{C} \) may be analyzed separated, then combined through a strong performance theorem guaranteeing good parallel running time. This result applies to the broad class of dynamically multithreaded computations. We achieve the runtime theorem through the novel technique of implicit batching coupled with an efficient runtime scheduler.

**Implicit batching.** This paper focuses on the novel technique of implicit batching, which achieves benefits of both concurrent and batched data structures. In implicit batching, the programmer provides two components: (1) a parallel program \( \mathcal{C} \) containing parallel accesses to a abstract data type \( \mathcal{D} \), and (2) a batched data-structure implementing the data structure \( \mathcal{D} \). The scheduler dynamically and transparently organizes the program’s parallel accesses to the data structure into batches, with at most one batch executing at a time.

Using implicit batching gives the benefits of batched data structures without restructuring the enclosing program \( \mathcal{C} \). The scheduler is responsible for grouping any concurrent accesses to the abstract data type \( \mathcal{D} \) into batches and invoking the appropriate implementation of a batched operation. The data structure’s batched operation may be implemented using dynamic multithreading (see Section 3 for examples). The data-structure’s implementation need not cope with concurrency since at most one batch is executing at any time, and hence locks or atomic operations may be omitted. The scheduler handles all synchronization and communication between the parallel program \( \mathcal{C} \) and the data structure \( \mathcal{D} \).

Implicit batching closely resembles flat combining [21], where each concurrent access to a data-structure queues up in a list of operation records, and this list of records (i.e., a batch) is later executed sequentially. Implicit batching may be viewed as a generalization of flat combining in that it allows parallel implementations of batched operations, instead of only a sequential one allowed by flat combining. Due to sequential batches, flat combining does not guarantee provable speedup guarantees. However, flat combining has been shown to be more efficient in practice than some of the best concurrent data structures under certain loads. Viewing flat combining as a specific implementation of implicit batching, already shows the practical effectiveness of implicit batching — this paper focuses on obtaining a provably good runtime theorem.

**Scheduler and performance theorem.** Implicit batching poses its own challenges for performance analysis. For a parallel program using implicit batching, which sequence of batches should be analyzed? What overhead does the scheduler incur when creating batches? In general, the performance of a parallel program using implicit batching depends on the particular runtime scheduler used to execute the program.

To yield a performance theorem, we propose \textsc{Batcher}, a work-stealing scheduler designed for implicit batching. Given a dynamically multithreaded program \( \mathcal{C} \) that makes parallel accesses to an ADT \( \mathcal{D} \), and a batched implementation of \( \mathcal{D} \), it yields the following bound, proven in Section 5:

**Theorem 1.** Consider a dynamically multithreaded program \( \mathcal{C} \) having \( T_1 \, \text{work} \) and \( T_w \, \text{span} \). Let \( n \) be the total number of data-structure operations ( accesses to ADT \( \mathcal{D} \)), and \( m \) be the maximum number of data-structure operations along any sequential dependency chain. For the given implementation of \( \mathcal{D} \), let \( W(n) \) be the worst-case total work for \( n \) data-structure operations grouped arbitrarily into batches, and let \( s(n) \) be the worst-case span of a parallel size-\( P \) batched operation.\(^3\) Then the expected running time of

\(^3\)We employ only binary forking, so \( s(n) \geq \log P \) implicitly.
this program on \( P \) processors using BATCHER\(^4 \) is at most
\[
O\left( \frac{T_1}{P} + T_\infty + \frac{W(n) + ns(n)}{p} + ms(n) \right).
\]

An important feature about this bound is that \( T_1 \) and \( T_\infty \) are the work and span of the core program \( C \), independent of the data structure implementation. Similarly, \( n \) and \( m \) count the data-structure calls in the program, and depend only on the program \( C \), not the data structure implementation. Moreover, \( s(n) \) and \( W(n) \) are performance measures of the batched implementation \( D \) of the data structure, independent of the enclosing program. We are thus essentially adding the program’s cost to the data structure’s cost. This bound also applies when the analysis of the batched data structure is amortized, through a more general definition of \( s(n) \) (see Section 2 for definitions). For many parallel batched data structures (see Section 3 for examples), this performance theorem implies nearly linear speedup.

The remainder of this paper is organized as follows. Section 2 presents the theoretical model we use to analyze parallel programs that make accesses to parallel data structures. Section 3 provides a high-level overview of BATCHER and applies the performance bound to example batched data structure. Section 4 presents the BATCHER scheduling algorithms, which is analyzed in Section 5; we built a prototype implementation of BATCHER and show preliminary experiments in Section 7. Section 6 discusses related work on using data structures in parallel.

2. DEFINITIONS AND ANALYTIC MODEL

Recall that a programmer provides two inputs to the BATCHER scheduler: (1) A parallel program \( C \) that makes parallel accesses to an abstract data type \( D \), and (2) a batched data structure that implements \( D \) and need only support one batch at a time. This section defines how the parallel program and the batched data structure are modeled.

Execution dag model. In the absence of data-structure operations, the execution of a dynamically multithreaded computation can be modeled as a directed acyclic graph (dag) that unfolds dynamically (see [11, Ch. 27]). In this execution dag, each node represents a unit-time sequential subcomputation, and each edge represents control-flow dependencies between nodes. A node that corresponds to a “fork” has two\(^5 \) outgoing edges, and a node corresponding to a “join” has two or more incoming edges.

A scheduler is responsible for choosing which nodes to execute on each processor during each timestep. The scheduler may only execute ready nodes — those unexecuted nodes whose predecessors have all been executed. The convenient feature about the computation dag is that it models the control-flow constraints within the program without capturing the specific choices made by the scheduler. The dag unfolds dynamically — only the immediate successors of executed nodes are revealed to the scheduler. This unfolding can also be nondeterministic. Hence the scheduler must make online decisions. All of our analyses are with respect to the a posteriori dag. The two key features of a dag are its work, which is the number of (unit-length) nodes in the dag, and its span, which is the length of the longest directed path through the dag.

\(^4\)Just as in standard work-stealing results, our theoretical bounds assume that the only synchronization of the input algorithm occurs through “synchs” or “joins”; the algorithm or data structure code itself does not use explicit synchronization primitives, e.g., locks or compare-and-swaps.

\(^5\)In general, forks may have arbitrary out-degree, but in this paper we pessimistically assume binary forking.

Extending the dag model to implicit batching. We first model the batched data structure that implements \( D \). An implementation of a batched operation is itself a parallel (sub)computation that may include forks and joins. We thus model the execution of each batch \( A \) by its own batch dag \( G_A \). We use the terms batch work, denoted by \( W_A \), and batch span, denoted by \( s_A \), to refer to the work and span of the batch dag, respectively.

To analyze a batched data structure as a whole, we consider worst-case sequences of arbitrary batches, such that the total number of data structure operations across all batches is \( n \), and each batch contains at most \( P \) data structure operations. We define the data-structure work, denoted by \( W_P(n) \), to be the maximum total work of any such sequence of batches. We also define the data-structure span, denoted by \( s_P(n) \), to be the worst-case span of any batch dag \( A \) in any such sequence subject to the the restrictions that \( W_A/s_A = O(P) \), meaning that the batch has limited parallelism. In the case when the data structure’s analysis is not amortized, the data-structure span may be stated more concisely as the worst-case span of any batch dag that represents a size-\( P \) batch, since all batches of the same size have the same span. For data structures with amortized analysis, however, batches with the same number of operations may have different spans — therefore, the batch span is defined in terms of the parallelism of the batch dag rather than the number of operations in the batch. Since \( P \) (the number of workers) is static throughout this paper, we use \( W(n) \) and \( s(n) \) as shorthands for \( W_P(n) \) and \( s_P(n) \). Note that whereas data-structure work corresponds to the total work of all batches that cumulatively contain \( n \) operations, the data-structure span corresponds to the span of a single batch with \( P \) operations. Thus far we have not considered a program that makes accesses to the data structure, we have only considered the data structure implementation. It should thus be clear that \( W(n) \) and \( s(n) \) are metrics of the data structure implementation itself.

We model the enclosing program \( C \), which makes parallel calls to a data structure (these operations will be implicitly batched), as another kind of dag, called the core dag \( G \). A core dag is just like a standard execution dag, except that it includes two kinds of nodes. Each data-structure operation (that is to be implicitly batched) is represented by a special data-structure node. All other non-data-structure nodes in the dag are called core nodes. Whereas all core nodes by definition take unit-time to execute on a processor, the data-structure nodes represent blocking calls that may take longer to complete. Our metrics for the core dag, however, avoid this issue — we define the core work, which we generally denote by \( T_1 \), to be the number of nodes in the core dag, and the core span, denoted by \( T_\infty \), to be the longest path through the core dag in terms of number of nodes. We also generally use \( n \) to refer to the number of data-structure nodes in the core dag, and \( m \) to denote the maximum number of data-structure nodes falling along any directed path through \( G \). Although the core dag includes data-structure nodes whose “execution times” are not defined, the metrics \( T_1, T_\infty, n, m \) are functions of only the core program, not the implementation of batched operations.

No extra dependencies between data-structure nodes? It may be surprising that modeling the core dag and batch dags separately as described throughout this section can be sufficient for the analysis of any scheduler. A priori, one might expect execution-dependent “happens-before” relationships across all data-structure calls, particularly since the scheduler must group operations into batches. Moreover, one might be surprised that the “length” of data-structure nodes is not modeled anywhere. Nevertheless, in Section 5 we prove that this simple model is sufficient for the BATCHER scheduler, which is a key contribution of the paper.
3. IMPLICIT BATCHING IN BATCHER

This section overviews implicit batching in the context of the BATCHER scheduler with respect to the core and batch dag described in Section 2. The specific algorithms employed by the scheduler itself are deferred to Section 4. This section also gives a simple example of a program using an implicitly batched data structure to provide concrete examples of applying the performance theorem.

**Programming Interface.** BATCHER provides distinct interfaces to the algorithm programmer, who writes a program to the algorithm programmer, who writes a program $C$ that makes parallel accesses to ADT $\mathcal{D}$; and the data-structure programmer, who provides the batched implementation of ADT $\mathcal{D}$. The runtime system stitches together these interfaces and does the scheduling. Figures 1 and 2 (discussed later in this section) show a simple example program making $n$ parallel increments to a shared counter using this interface style.

To perform a data-structure operation, the program $C$ makes a call into the runtime system, denoted by Batcherify here. As far as the algorithm programmer is concerned, Batcherify$(\text{corresponding to an data-structure node in the core dag})$ resembles a normal procedure call to access a concurrent data structure, and the control flow blocks at this point until the operation completes.

A BATCHER data structure, on the other hand, must provide an implementation of a parallel batched operation, which we denote by Bop. Since Bop is a batched implementation, it takes as input a set (i.e., an array) of operations to the ADT $\mathcal{D}$ to perform. Note that Bop is itself a dynamically multithreaded function that can use spawn/sync or parallel loops to generate parallelism. A single invocation of the Bop function corresponds to a single batch dag.

**Batching.** At a high level, calls to Batcherify correspond to data-structure nodes and BATCHER is responsible for implicitly batching these data structure operations and then executing these batches by calling Bop. When a worker $p$ encounters a data-structure node $u$ (i.e., $p$ executes a call to Batcherify), $p$ alerts the scheduler to the operation by creating an operation record op for that operation and placing it in a particular memory location reserved for this processor. Eventually, op will be part of some batch $A$ and the scheduler will call Bop on $A$. Unlike core nodes, however, the data-structure node $u$ does not become ready until after this call to Bop returns, that is, the operation corresponding to $u$ is actually performed on the data structure as part of a batch. Thus from the perspective of the core program, a data-structure node $u$ has the same semantics as a blocking access to a concurrent data structure.

Inherent to implicit batching is the idea that the batch the scheduler invokes only one batch at a time. Hence the data-structure implementation need not cope with concurrency, simplifying the data-structure design. The following invariant states this property for BATCHER.

**Invariant 1.** At any time during a BATCHER execution, at most one batch is executing.

Finally, whenever an operation record is created and no batch is currently in progress, BATCHER immediately launches a new batch; it does not wait for a certain number of operations to accrue; this decision is important for the theoretical analysis. Therefore, batches can contain as few as one operation. Launching a batch includes some (parallel) setup to gather all operation outstanding operation records, executing the provided (parallel) batched operation Bop thereby inducing a batch dag, and some (parallel) cleanup after completing. Since the setup/cleanup overhead is scheduler dependent, we account for the overhead separately, and the batch dag comprises only the steps of Bop.

**Intuition behind the analysis.** The analysis of BATCHER (Section 5) relies on specific features of the scheduling algorithm (Section 4). Nevertheless, we have already exposed one significant difficulty: since batches launch as soon as possible, some batches may contain just a single data-structure node. If this were true for every batch, then all operations would be sequentialized according to Invariant 1, and it would seem impossible to show good speedup. In addition, the batch setup and cleanup overhead is the same, regardless of batch size; therefore, having many small batches may incur significant overhead.

Fortunately, small batches fall into two cases, both being good.
(1) Many data structure nodes accrue while a small batch is executing. These will be part of the next batch, meaning that the next batch will be large and make progress toward the batch work $W(n)$.
(2) Not many data structure nodes are accruing. Then the core dag is not blocked on too many data-structure nodes, and progress is being made on the core work $T_1$. In both cases, the setup and cleanup overhead of the small batch can be amortized either against the work done in the next batch or the work done in the core dag.

**Example and applying the performance bound.** To understand the BATCHER performance bound (Theorem 1), let us turn to some specific examples. We are not developing new batched data structures here — the point is only to illustrate the power of batched data structures, and to see how to apply the bound.

As a simple example, consider a core program that makes $n$ completely parallel increments to a shared counter, as given by Figure 1. This example is for illustration only, and is not intended to be very deep. This program has $\Theta(n)$ core work and $\Theta(\lg n)$ core span (with binary forking). The shared counter is an abstract data type that supports a simple operation INCREMENT, which atomically adds a value (possibly negative) to the counter and returns its current value.

**Concurrent counter.** A trivial concurrent counter uses atomic primitives like fetch-and-add to INCREMENT. If the primitive is mutually exclusive (which is true for fetch-and-add on current hardware), then $n$ INCREMENTs take $\Omega(n)$ time. The total running time of the program is thus $\Omega(n)$ regardless of the number of processors.

One could instead use a provably efficient concurrent counter, e.g., by using the more complicated combining funnels [37, 38]. Doing so would indeed yield a good overall running time, but these techniques are not applicable to more general data structures. As we shall see next, the implicitly batched counter achieves good asymptotic speedup with a trivial implementation.

**Batched counter.** Figure 2 shows a sample batched counter. Here, when the core program makes an INCREMENT call, it creates an operation record which is handed-off to the scheduler. The scheduler later runs the batch increment Bop on a set of increments. The main subroutine of the batched operation is “parallel prefix sums”,

**Invariant 2.** In a BATCHER execution, batches contain at most $P$ data-structure nodes.

|
1 parallel_for i = 1 to n
2 do B[i] = INCREMENT(A[i])

Figure 1: A parallel loop that performs \( n \) parallel updates to a shared counter. Here, \( A[1...n] \) is an array of values by which to increment (or decrement if negative) the counter, and \( B[1...n] \) holds any return values from the \text{INCREMENTS}.

3 struct OpRecord {int value; int result;}
4 increment(int x)
5 op.value = x
6 BATCHIFY(this, op) //ask the scheduler to batch op
7 return op.result

BOP(OpRecord D[1...size])
8 let v be the value of the counter
9 D[1’s value field] = v + D[1’s value]
10 perform parallel-prefix-sums on value fields of D[1...size],
   storing sums into result fields of D[1...size]
   //now D[i’s result] = \( \sum_{k=1}^{i} D[k]’s \) value
11 set the counter to D[size]’s result

Figure 2: A batched-counter implementation. As we shall see in Section 4, line 6 logically blocks, but the processor does not spin-wait. The \text{BOP} is called by the scheduler automatically.

which \text{in parallel} computes \( \sum_{k=1}^{i} D[k] \) for each \( i \). It is easy to prove that returning \( \sum_{k=1}^{i} D[k] \) yields linearizable [25] counter operations. Prefix sums are a commonly used and powerful primitive in parallel algorithms, and hence we consider this 4-line implementation of \text{BOP} to be trivial. Adaptations of Ladner and Fischer’s approach to prefix sums [28] to the fork-join model have \( O(x) \) work and \( (\lg x) \) span for \( x \) elements.

To analyze the execution of this program using \text{BATCHER}, we need only bound \( W(n) \), the total work of arbitrarily batching \( n \) operations, and \( s(n) \), the span of a batched operation that processes \( P \) operation records (performs \( P \) increment operations). Since the work of prefix sums is linear, we have \( W(n) = \Theta(n) \). Since a size-\( P \) batch has \( O(\lg P) \) span (dominated by prefix sums), we have \( s(n) = O(\lg P) \). We thus get the bound \( O(\frac{T_1 + n\lg P}{P} + m\lg P + T_m) \) for \( n \) \text{INCREMENTS}, with \( m \) work along any path. The core dag of Figure 1 has \( T_1 = O(n) \), \( T_m = O(n\lg n) \), \( m = 1 \), so we have a running time of \( O(\frac{\lg P}{P} + \lg n) \) for \( n > P \). This nearly linear speedup is much better than for the trivial counter.

Applying \text{BATCHER} to a search tree. There exists an efficient batched 2-3 tree [33] in the PRAM model, and it is not too hard to adapt this algorithm to dynamic multithreading. The main challenge in a search tree is when all insertions occur in the same node of the tree, e.g., when inserting identical keys. The main idea of this batched search tree is to first sort the new elements, then insert the middle element and recurse on each half of the remaining elements. This process allows for each of the new keys to be separated by existing keys without concurrency control. It is not obvious how to leverage the same idea in a concurrent search tree.

See [33] for details of the batched search tree. Suffice it to say that a size-\( x \) batch is dominated by two steps: 1) a parallel search for the location of each key in the tree, having \( O(x\lg n) \) work and \( O(\lg n + \lg x) \) span, and 2) a parallel sort of the \( x \) keys, having \( O(x\lg x) \) work. The data-structure span is thus \( s(n) = O(\lg n + \text{sort}(P)) \), where \( \text{sort}(P) = O(\lg P\lg P) \) [10] is the span of a parallel sort on \( P \) elements in the dynamic-multithreading model. The data-structure work \( W(n) \) is maximized for \( n/P \) batches of size \( x = P \), yielding \( W(n) = O(n\lg n) \) data-structure work. Applying Theorem 1, we get a running time of \( O(\frac{T_1 + W(n) + s(n) + m\lg n}{P} + m\lg n + m\lg P\lg P + T_m) \). For large enough \( n \) (specifically, \( n = \Omega(P^2/\lg P) \)), this reduces to \( O(\frac{\lg n + m\lg n + T_m}{P}) \), which is asymptotically optimal in the comparison model and provides linear speedup for programs with sufficient parallelism. For instance, a program obtained by substituting the increment operation with an insert in Figure 1 would yield the running time of \( O(n\lg n/P) \), implying linear speedup, even though the program only performs data structure accesses.

Amortized LIFO stack. We now briefly describe an example, namely a LIFO stack, which has amortized performance bounds. The data structure is an array that supports two operations: a \text{PUSH} that inserts an element at the end of the array, and a \text{POP} that removes and returns the last element. Such an array can be implemented using a standard table doubling [11] technique, whereby the underlying table is rebuilt (in parallel) whenever it becomes too full or too empty. To \text{PUSH} a batch of \( x \) elements into an \( n \)-element array, check if \( n + x \) elements fit in the current array. If so, in parallel simply insert the \( x \)th batch element into the \( (n + i) \)th slot of the array. If not, first resize the array by allocating new space and copying all existing elements in parallel. \text{POPs} can be simultaneously supported by breaking the batch into a \text{PUSH} phase followed by a \text{POP} phase.

To analyze this data structure, the (amortized) work of a size-\( x \) batch is \( \Theta(x) \), yielding \( W(n) = \Theta(n) \) (worst case). The work of any individual batch, however, can be as high as \( \Theta(n) \) when a table doubling occurs. More importantly, any batch \( A \) that has \( w_A \) batch work has batch span \( s_A = O(\lg w_A) \). Hence any batch \( A \) that performs \( w_A \geq P^2 \) work has parallelism \( w_A/s_A = \Omega(P^2/\lg P) \). We thus conclude that the data-structure span is \( s(n) = O(\lg(P^2)) = O(\lg P) \). Plugging these bounds into Theorem 1, we get a total running time of \( O(\frac{T_1 + n\lg P}{P} + m\lg P + T_m) \).

4. THE BATCHER SCHEDULER

This section presents the high-level design of the \text{BATCHER} scheduler, a variant of a distributed work-stealing scheduler. We use \( P \) to refer to the number of \text{workers}, or threads/cores, given to the scheduler. Since \text{BATCHER} is a distributed scheduler, there is no centralized scheduler thread and the operation of the scheduler can be described in terms of state-transition rules followed by each of the \( P \) workers. First, we describe the internal state that \text{BATCHER} maintains in order to implicitly batched data-structure operations and to coordinate between executing the core and batch dags. We then describe how batches are launched and how load-balancing is done using work-stealing.

\text{BATCHER} state. The \text{BATCHER} scheduler maintains three categories of shared state: (1) collections for tracking the implicitly batched data-structure operations, (2) status flags for synchronizing the scheduler, and (3) queues for each worker tracking execution-dag nodes (see Section 2) and used by work stealing. With the exception of one global flag, most of this state is distributed across workers, with each worker only managing specific updates according to the provided rules that define the scheduler.

To track active data-structure nodes, \text{BATCHER} maintains two arrays. When a worker encounters a data-structure node (executes a call to \text{BATCHIFY}(op)), instead of accessing the data-structure di-
rectly, an operation record \( op \) is created and placed in the *pending array* and the data-structure node is suspended. BATCHER guarantees that each worker has at most one suspended node / pending operation at any time; therefore this pending array may be maintained as a size-\( P \) array, with a dedicated slot for each of the \( P \) workers. BATCHER also maintains a *working set*, which is a densely packed array of all the operation records being processed as part of the currently executing batch.

To synchronize batch executions, BATCHER maintains a single global active-batch flag. In addition, each worker \( p \) has a local *work-status* flag (denoted \( \text{Status}[p] \)), which describes the status of \( p \)'s current data-structure node. BATCHER guarantees that at any instant, each worker has at most one data-structure node \( u \) that it is trying to execute. For concreteness, think in terms of the following four states for worker status \( \text{Status}[p] \):

- *pending*, if \( p \) has an operation record \( op \) for a suspended data structure node \( u \) in the pending array.
- *executing*, if \( p \) has an operation record \( op \) for a suspended data structure node \( u \) in the working set, i.e., a batch containing \( u \) is currently executing.
- *done*, if the batch \( A \) containing \( u \) has completed its computation, but \( p \) has not yet resumed the suspended suspended node \( u \).
- *free*, if \( p \) has no suspended data-structure node.

If \( \text{Status}[p] \) is pending, executing, or done, we say \( p \) is *trapped* on operation \( u \). Otherwise, we say \( p \) is *free*.

Finally, BATCHER maintains two deques of ready nodes on each worker: a *core deque* for ready nodes from the core dag, and a *batch deque* for ready nodes from a batch dag. In particular, the deques in BATCHER obey the following invariant:

**Invariant 3.** Ready nodes belonging to the core dag \( G \) are always placed on some worker’s core deque, whereas ready nodes that belong to some batch \( A \)’s batch dag \( G_A \) are always placed on some worker’s batch deque.

Associated with these deques, each worker \( p \) also has an *assigned node* — the node that \( p \) is currently executing. At any instant, the assigned node of \( p \) may conceptually be associated with either the core deque or the batch deque, depending on the type of node being executed by that worker. Some workers may be executing core nodes while others are executing batch nodes.

**Background: traditional work stealing.** In a traditional work-stealing scheduler [6], each of \( P \) workers maintains a core deque of ready nodes, and at any time, a worker \( p \) has at most one assigned node \( u \) that the worker is currently executing. When \( u \) finishes, it may enable at most 2 nodes. If 1 or 2 node(s) are enabled, \( p \) assigns one to itself and places the other (if any) at the bottom of its deque. If none are enabled, then \( p \) removes the node at the bottom of its deque and assigns it to itself. If \( p \)'s deque is empty, then \( p \) becomes a *thief*, randomly picks a *victim* worker and steals from the top of the victim’s deque. If the victim’s deque is not empty, then the steal attempt *succeeds*, otherwise it *fails*.

**BATCHER algorithm.** BATCHER uses a variant of work stealing, with some augmentations to support implicit batching. Free workers and trapped workers behave quite differently. Initially all workers are free, and all ready nodes belong to the core dag, and BATCHER behaves similarly to traditional work stealing. As data-structure nodes are encountered, however, the situation changes. The scheduling rules are outlined in Figure 3 and described below.

Free workers behave closest to traditional work stealing. A free worker is allowed to execute any node (core or batch), but it only steals if both of its deques are empty. Specifically, if either deque is nonempty, the worker executes a node off the nonempty deque, and

When \( p \) is free and both deques are empty:

- steal from random victim, using alternating-steal policy

When a data-structure node \( u \) is assigned to (free) worker \( p \):

- insert operation record into *pending* \( p \)
- \( \text{Status}[p] = \text{pending} \)
- suspend \( u \)
- \( // p \) is now trapped

When \( p \) is trapped and its batch deque is empty:

- if \( \text{Status}[p] = \text{done} \)
  - then \( \text{Status}[p] = \text{free} \)
  - resume executing the core deque from suspended data-structure node \( u \)
  - \( // p \) is now free
- else if global batch flag = 0 and compare-and-swap(global batch flag, 0, 1)
  - then run LAUNCHBATCH
  - else steal from random victim’s batch deque

**Figure 3: Scheduler-state transition rules invoked by workers with empty deques.** When the appropriate deque is not empty, the worker removes the bottom node from the deque and executes it.

any newly enabled nodes are placed on the same deque. BATCHER thus maintains the following invariant:

**Invariant 4.** Workers that have *free* status in BATCHER can have at most one of their deques non-empty, i.e., they have nodes either on the batch deque or core deque, but not both.

If both deques are empty, however, the free worker performs a steal attempt according to an alternating-steal policy: each worker’s \( k \)th steal attempt (successful or not) is from a random victim’s core deque if \( k \) is even, and from a random victim’s batch deque if \( k \) is odd. The alternating-steal policy is important to achieve the performance bound in Section 5.

When a (free) worker \( p \) executes a data-structure node \( u \), \( p \) first inserts the corresponding operation record \( op \) in its dedicated slot in the pending array, and then it changes its own status to *pending*. At this point, the \( p \) becomes trapped on \( u \), and according to Invariant 4, it has an initially empty batch deque.

Unlike free workers, which are allowed to execute both core and batch work, trapped workers are only allowed to execute nodes from a batch deque. If a trapped worker \( p \) has a nonempty batch deque, it simply selects a node off the batch deque as in traditional work stealing. If it has an empty batch deque, however, it performs the following step. First, it checks whether its data-structure node \( u \) has finished, i.e., if \( \text{Status}[p] = \text{done} \). If so, it changes its own status to *free* and resumes from the suspended data-structure node on the core deque. Otherwise, it checks the global batch status flag and tries to set it using an atomic operation if no batch is executing.

If successful in setting the flag, \( p \) “launches” a batch. If it is unsuccessful (someone else successfully set the flag and launched a batch) or if a batch is already executing (status flag was already 1) it simply tries to steal from a random victim’s deque. BATCHER guarantees that if no batch is executing, then all workers have status either pending, done or free; therefore, only pending workers can succeed in launching a new batch.
L A U N C H B A T C H ( )
1 parallel_for i = 1 to P
  do if Status[i] = pending then Status[i] = executing
2 compact all executing op records, moving them from pending array to working set
  // using parallel prefix sums subroutine
3 execute BOp (the actual parallel batch) on records in working set
4 parallel_for i = 1 to P
  do if Status[i] = executing then Status[i] = done
    remove done op records from the working set.
5 reset global batch-status flag to 0

Figure 4: Pseudocode for launching a batch. This method executes as an ordinary task in a dynamic multithreaded computation, i.e., it may run using any number of workers between 1 to P workers, depending on how work-stealing occurs.

Launching a batch. Launching a batch corresponds to injecting the parallel task L A U N C H B A T C H (see Figure 4), i.e., by inserting the root of the subdag induced by this code on a worker’s batch deque. This process has five steps. First, the pending array is processed in parallel, changing the status of all pending workers to executing, thereby acknowledging the operation record. Second, the executing records are packed together in the working-set array, which can be performed in parallel using a parallel prefix sums computation. Third, the actual batched operation (BOp) is executed on the records in working set. Fourth, the pending array is again processed in parallel, changing the status of all executing workers to done. Finally, the batch-status flag is reset to 0. In practice, several of these steps can be merged, but we are not concerned about these low-level optimizations in this paper.

As mentioned above, launching a batch incurs some overhead, such as updating status fields and compacting the pending array into working-set, beyond the execution of the batched operation BOp itself. We refer to this overhead as the batch-setup overhead. Note that this set-up procedure is itself a dynamic multithreaded program with Θ(P) work and Θ( log P) span, primarily due to the cost of the parallel_for and parallel prefix sums computations over P elements. This set-up work is performed in exactly the same way as the batched operation BOp is performed — that is, the nodes of this procedure are placed on batch deques and are executed in parallel (via work-stealing) by workers working on these deques. Note, however, that for the purposes of the dag metrics, the overhead is not counted as part of the batch work, batch span, or data-structure span defined in Section 2; this omission is by design since the overhead is a function of the scheduler, not the input program. This fact is one of the challenges in proving that BATCHER has a good running time, and it is exacerbated by the fact that the overhead is as high for a batch containing 1 operation as it is for a batch containing P operations. Nevertheless, we shall show (Section 5) that BATCHER is provably efficient.

Not trapped long. The following lemma shows that a worker is not trapped for very long by a particular operation (at most 2 batches).

LEMMA 2. Once the operation record for a data-structure node u is put into the pending array, at most two batches execute before the node completes.

PROOF. Consider an operation u whose status changes at time t to pending. Any batch finishing before time t does not delay u. Any batch A launched after time t observes u in the pending array, and incorporates it in A and completes it; this accounts for one batch execution. According to Invariant 1, there can only be one batch that is launched before t and finishes after t, which accounts for the second batch.

Correctness of state changes. Each worker is responsible for changing its own state from done to free and free to pending. There is thus no risk of any races on these state changes. The changes from pending to executing and executing to done may be performed by an arbitrary worker, but these changes occur as part of the parallel computation L A U N C H B A T C H . Since L A U N C H B A T C H is itself race free and only one L A U N C H B A T C H occurs at a time (protected by the global batch-status flag), these transitions are also safe.

5. ANALYSIS OF BATCHER

We now analyze the performance of BATCHER. We first provide some definitions and the statement of the completion time bounds. Then we use a potential function argument to prove these bounds.

Definitions and theorem statements. We will analyze the running time using the computation dag G and the set of batch dags that represent batches generated due to implicit batching performed by BATCHER. We will analyze the running time using an arbitrary parameter τ, which will be later related to the data-structure span s(n). We define a few different types of batches. A batch A is τ-wide if its batch work is more than Pτ. A batch is τ-long if its batch span is more than τ. These definitions only count the work and span within the batched operations themselves, not the batch-setup overhead due to BATCHER. Since τ is implied, we often drop it and call batches wide or long. Finally, a batch is popular if it processes more than P/4 operation records; that is, it contains more than P/4 data structure nodes. A batch is big if it is either long, wide or popular, or if it occurs immediately before or after a long, wide or popular batch. All other batches are small.

The above definitions are with respect to individual batches that arise during an execution. We next define a property of the data structure itself, analogous to data-structure work (Section 2).

DEFINITION 1. Consider any sequence of parallel batched operations and a real value τ. The τ-trimmed span of the sequence of batches is the sum of the spans of the long batches in the sequence. The τ-trimmed span of a data structure, denoted by S(τ), is the worst-case τ-trimmed span for n data-structure nodes grouped arbitrarily into batches.

We now state our main theorem, a bound on the total running time of a BATCHER computation, which is proven at the end of this section. The restriction that τ ≥ log P arises from binary forking.

THEOREM 3. Consider a computation with T1 core work, Tω core span, and n data-structure nodes with at most m falling along any path through the dag. For any τ ≥ log P, let S(τ) and W(n) denote the worst-case τ-trimmed span and total work of the data structure, respectively. Then BATCHER executes the program in

\[ O\left(\frac{T_1 + W(n) + mτ}{P} + T_ω + S(τ) + mτ\right) \]

expected time on P processors.

This theorem holds for any τ ≥ log P; however, it does not provide intuition about which τ is best. There is a tradeoff: increasing τ increases Στ and mτ, but decreasing τ increases S(τ) since more batches become long. As we shall see at the end of this section, setting τ = s(n), the data-structure span (defined in Section 2), yields Theorem 1 as a corollary since other terms dominate S(τ).

Intuition behind the analysis. As with previous work-stealing analyses, our analysis separately bounds the total number of pro-
cessor steps devoted to various activities; in our case, these activities are core work, data-structure work, stealing (and failed steal attempts), and the batch-setup overhead. We then divide this total by \( P \), since each processor performs one processor step per timestep, to get the completion time.

It is relatively straightforward to see that the number of processor steps devoted to core work is \( T_1 \) and the number of time steps devoted to data structure work is \( W(n) \). The difficulty is in bounding the number of steal attempts and the batch set up overhead. To bound the number of steal attempts, we adopt a potential function argument similar to Arora et al.’s work-stealing analysis [2], henceforth referred to as ABP. In the ABP analysis, each ready node is assigned a potential that decreases geometrically with its distance from the start of the dag. For traditional work stealing, one can prove that most of the potential is in the ready nodes at the top of the deques, as these are the ones that occur earliest in the dag. Therefore, \( \Theta(T) \) random steal attempts suffice to process all of these nodes on top of the deques, causing the potential to decrease significantly. Therefore, one can prove that \( O(P T_n) \) steal attempts are sufficient to reduce the potential to 0 in expectation.

The ABP analysis does not directly apply to bounding the number of steal attempts by BATCHER for the following reason. When a data structure node \( u \) becomes ready and is assigned to worker \( p \), \( p \) places the corresponding operation record in the pending array and \( u \) remains assigned (control flow does not go past \( u \)) until results from \( u \) are available. But \( u \) may contain most of the potential of the entire computation (particularly if \( p \)'s deque is empty; in this case \( u \) has all of \( p \)'s potential). Since \( u \) cannot be stolen, steals are no longer effective in reducing the potential of the computation until the batch containing \( u \) completes. To cope with this difficulty, we apply different progress arguments to big batches and small batches.

Bounding steal attempts during big batches: For big batches, we apply the ABP potential function to each batch’s computation dag. Nodes in a batch dag are never “suspended” in the way data-structure nodes are, so the ABP argument applies nearly directly. We charge this case against the \( \tau \)-trimmed span or the data-structure work. (As a technical detail, we must also show that \( P \) steal attempts overall equate to \( \Omega(P) \) steal attempts from batch deques in order to complete the argument.)

Bounding other steal attempts: Unfortunately, small batches do not contribute to the \( \tau \)-trimmed span, so the above approach does not apply. Instead, we apply extra machinery to bound these steal attempts. The intuition is that if many steal attempts actually occur during a small batch, then the batch should complete quickly (i.e., within \( O(\tau) \) timesteps). On the other hand, if few steal attempts occur then the workers are being productive anyway, since they are doing useful work (either core work or data-structure work) instead of stealing. To apply this intuition more formally within the ABP framework, we augment each data-structure node to comprise a chain of \( \tau \) “dummy nodes,” which captures these cases by appropriate potential decreases in the augmented dag.

Set up: dag augmentation and potential function. We create an augmented computation dag, the \( \tau \)-execution dag \( G(\tau) \), by adding a length \( \Theta(\tau) \) chain of dummy nodes before each data-structure node in the computation dag. The work of this dag is \( W_G(\tau) = T_1 + O(n\tau) \) and span is \( S_G(\tau) = T_n + O(n\tau) \).

For the purpose of the analysis, we suppose the scheduler executes the augmented dag instead of the original dag. The scheduler operates with one corresponding difference: when a worker encounters a data-structure node, this node remains assigned to the worker, but \( \Theta(\tau) \) nodes of the dummy-node chain are placed at the bottom of its core deque. If a worker \( p \) steals from another worker \( p' \)’s core deque and a dummy node is on the top of that deque, then \( p \) steals and immediately processes the dummy node. This steal is considered a successful steal attempt. When a worker returns from a batch, all the dummy nodes on the bottom of its deque disappear. Note that dummy nodes are only for accounting. Operationally, this runtime system is identical to the one described in Section 4, except the analysis now just counts some unsuccessful steals as successful steals. More precisely, whenever a dummy node is stolen from a victim’s deque, the corresponding steal in the real execution is unsuccessful because the victim’s deque was empty.

We now define the potentials using this augmented dag. Each node in \( G \) has depth \( d(u) \) and weight \( w(u) = S_G - d(u) \). Similarly, for a node \( u \) in the batch dag \( G_A \), \( d(u) \) is its depth in that dag, and its weight is \( w(u) = s_A - d(u) \). The weights are always positive.

**Definition 2.** The potential \( \Phi_u \) of a node \( u \) is \( 3^{2^{w(u)-1}} \) if \( u \) is assigned, and \( 3^{2^{w(u)}} \) if \( u \) is ready.

The core potential of the computation is the sum of potentials of all (ready or assigned) nodes \( u \in G \). The batch potential is the sum of the potentials of all \( u \in G_A \) where \( A \) is the currently active batch (if one exists). The following structural lemmas follow in a straightforward manner from the arguments used throughout the ABP paper [2], so we state them without proof here.

**Lemma 4.** The initial core potential is \( 3^6 \) and it never increases during the computation.

**Lemma 5.** Let \( \Phi(t) \) denote the potential of the core dag at time \( t \). If no trapped worker’s deque is empty, then after \( 2P \) subsequent steal attempts from core deques the core potential is at most \( \Phi(t)/4 \) with probability at least 1/4.

**Lemma 6.** Suppose a computation (core or batch) has span \( S \), and that every “round” decreases its potential by a constant factor with at least a constant probability. Then the computation completes after \( O(S) \) rounds in expectation, and the total number of rounds is \( O(S + \log(1/\varepsilon)) \) with probability at least \( 1 - \varepsilon \).

The following two lemmas extend Lemmas 4 and 5 to batch potentials. The proofs of these lemmas can also be derived from ABP proofs in a similar manner.

**Lemma 7.** The batch potential \( \Phi_A \) increases from 0 to \( 3^{2S_A} \) when \( A \) becomes ready, and never increases thereafter.

**Lemma 8.** Let \( \Phi_A(t) \) be the potential of batch \( A \) at time \( t \). After \( 2P \) subsequent steal attempts from batch deques, the potential of \( A \) is at most \( \Phi_A(t)/4 \) with probability at least 1/4.

Since different arguments are required for big and small batches, we partition steal attempts into three categories. A big-batch steal attempt is any steal attempt that occurs on a timestep during which a big batch is executing. A trapped steal attempt is a steal attempt made by a trapped worker (a worker whose status is not free) on a timestep when no big batch is active. A free steal attempt is a steal attempt by a free worker (a worker whose status is free) on a victim’s deque, the corresponding steal in the real execution is unsuccessful because the victim’s deque was empty.

**Lemma 9.** (of [2], but the rest falls to interproof discussion within the paper.)
a timestep when no big batch is active. We can now bound the different types of steal attempts and the batch-setup overhead.

**Big-batch steal attempts.** The big-batch steal attempts are bounded by the following lemma. The proof of this lemma is the most straightforward of the three cases.

**Lemma 9.** The expected number of big-batch steal attempts is $O(n\tau + PS_2(n) + W(n))$.

**Proof.** We first prove that if $L$ is the set of big batches, the expected number of big batch steal attempts is $O(P\sum_{A \in L} S_A)$. Consider a particular big batch $A$. When the first round starts, the potential of the batch is $\frac{3}{2}S_A$ (Lemma 7). Divide the steal attempts that occur while the batch is executing into rounds of 4P steal attempts, except for the last round, which may have fewer. While $A$ is executing, at least half the steal attempts are from batch deques, since all the trapped steals are from batch deques, and half the free steals are from batch deques by the alternating steal policy. Therefore, in every round, at least $2P$ steal attempts are from batch deques. Applying Lemma 8, the potential of the batch decreases by a constant factor with probability $1/4$ during each round. Therefore, applying Lemma 6, we can conclude that there are expected $O(S_A)$ rounds while $A$ is active.

We use linearity of expectation to add over all big batches. We first add over long, wide and popular batches. The total span of long batches is $S_L(n)$ by definition. There are at most $W(n)/P$ wide batches, and at most $n/P$ popular batches. If they are not also long, they have span less than $\tau$. We triple the number to account for batches before and after long, wide or popular batches. Therefore, we can see that there are the number of rounds during big batches that can trap a worker, and over $P$ batches these rounds have small spans, chances are most small batches finish before any trapped worker runs out of dummy nodes.

**Free steal attempts.** Here, each “round” consists of $4P$ consecutive free steal attempts (during which no big batch is active). Recall that when a worker becomes trapped, it places $\Theta(\tau)$ dummy nodes on the bottom of its core deque. We say that a round is **bad** if, at the beginning of the round, some trapped worker’s core deque is empty (does not have any core nodes or dummy nodes). Otherwise, a round is **good**. Note that bad rounds only occur while some batch is executing; otherwise no worker is trapped. We bound good and bad rounds separately.

Good rounds do not have the problem of too much potential being concentrated in a suspended data-structure node of a trapped worker. During a good round, there is more potential in the dummy nodes than the suspended data-structure node itself, and steal attempts reduce potential.

**Lemma 10.** The number of good rounds is $O(S_G)$ in expectation and $O(S_G + \lg(1/\epsilon))$ with probability at least $1 - \epsilon$. Therefore, the number of free steal attempts in good rounds is $O(PS_G)$ in expectation and $O(PS_G + P\lg(1/\epsilon))$ with probability at least $1 - \epsilon$.

**Proof.** During a good round, there are $4P$ total steal free steal attempts, and thus by the alternating steal policy, half of these ($2P$) are from core deques. Since no trapped worker’s deque is empty when the round begins, we can apply Lemma 5 to conclude that each round decreases the core potential by a constant factor with a constant probability; being interrupted by a big batch only decreases the potential further. We can then apply Lemma 6 to conclude that there are $O(S_G)$ rounds show the requisite bound; multiplying by $P$ gives the bound on the number of free steal attempts during good rounds.

We can now bound the number of bad rounds using the following intuition. The number of bad rounds is small since small batches have small spans, chances are most small batches finish before any trapped worker runs out of dummy nodes.

**Lemma 11.** The total number of free steal attempts during bad rounds is $O(n\tau)$ in expectation.

**Proof.** A worker $p$ places $\Theta(\tau) = b\tau$ dummy nodes, for constant $b$, on its core deque when it becomes trapped. There is a bad round if its core deque is stolen from at least $b\tau$ times before $p$ becomes free again. There are two cases:

**Case 1:** worker $p$ is trapped for $k\tau$ rounds, for some constant $k$; applying a Chernoff bound, during $k\tau$ rounds, each core deque is stolen from $< k_1\tau + k_2\lg P$ times with probability $> (1 - 1/P^2)$ for appropriate settings of constants $k_1$ and $k_2$. If $\tau \geq \lg P$ and $b = k_1 + k_2$, then $p$'s deque runs out of dummy nodes with probability $< 1/P^2$.

**Case 2:** worker $p$ is trapped for more than $k\tau$ rounds, for constant $k$. From Lemma 2, we know that $p$ is trapped for at most 2 batches, say $A_1$ and $A_2$. Therefore, at least one of $A_1$ and $A_2$, say $A_1$, must be active for more than $k\tau/2$ rounds. We first bound the number of rounds during which $A_1$ can be active, with high probability. If $A_1$ is active throughout a round, then there are at least $2P$ steal attempts from batch deques during the round $r$ (since half the free steal attempts hit batch deques) and Lemma 8 applies. If a batch starts or ends during $r$, its potential decreases by a constant factor trivially. We can then apply Lemma 6 to show that with probability $1 - \epsilon$ the batch $A_1$ is active for $O(S_{A_1} + \lg(1/\epsilon)) = O(\tau + \lg(1/\epsilon))$ rounds, since $A_1$ is not long. ($p$ is waiting for the small batch $A_2$; therefore, the preceding batch $A_1$ is also not long.) We know that $O(\tau + \lg(1/\epsilon))/k_1\tau + k_2\lg(1/\epsilon)$ for some constants $k_1$ and $k_2$; we set $\epsilon = 1/P^2$ and $k_2 = k_1 + 2k_2$. The probability that $A_1$ is active for $k\tau/2$ rounds is at most $1/P^2$. There can be at most $Pt$ bad rounds for $A_1$, since each round takes at least one timestep, and a small batch has at most $P$t work. Therefore, the expected number is at most $O(\tau/P)$.

Adding over the $n$ batches that can trap a worker, and over $P$ workers, gives us $O(n\tau)$ in total.

**Corollary 12.** Ignoring the batch-setup overhead, the expected number of steps taken by free processors when no big batch is active is $O(T_1 + W(n) + n\tau + PS_G)$.

**Proof.** A free worker is either working (at most $T_1 + W(n)$ steps) or stealing (bounded by Lemmas 10 and 11).

**Trapped steal attempts and batch-setup overhead.** We next analyze the steal attempts by trapped workers during small batches. The key idea is as follows. Recall that a worker is trapped by a batch $A$ only if it has a pending data structure node whose operation record is being processed by $A$ or will be processed by the succeeding batch $A'$ (see Lemma 2). If more than $P/2$ workers are trapped on a $A$, then either $A$ or $A'$ must be popular, in which case $A$ is called big. Therefore, at most $P/2$ workers be trapped by a small batch.

**Lemma 13.** The expected number of processor steps taken due to batch-setup overhead and trapped steal attempts is $O(T_1 + W(n) + n\tau + PS_G + PS_G(n))$.

**Proof.** The batch-setup overhead is $O(P)$ per batch. After it launches, each batch executes for at least 1 timestep and only one batch executes at a time. For big batches, during this one timestep,
the workers perform $P$ steps of either work (bounded by $T_H + W(n)$) or big batch steals (bounded by Lemma 9). We can amortize the batch-setup overhead against these $P$ steps. For small batches, at least $P/2$ processors are free and again they perform either work or free steals (bounded by Corollary 12), and we can amortize the batch-setup overhead against this quantity. Adding these gives us the bound on batch-setup overhead.

Even if we pessimistically assume that trapped workers do nothing but steal during small batches, since at least half the workers are free, we can amortize these steals against the steps taken by free workers which either work or steal or perform batch setup steps. □

Overall running time. We can now bound the overall running time. We combine the bounds from Lemmas 9, 10 and 11, and substitute $S_C = T_m + nrt$ and divide by $P$ (since there are $P$ workers performing these steps) to prove Theorem 3.

Proof of Theorem 3. From Lemmas 9, 10, 11 and 13, we know that the expected number of big-batch steal attempts is $O(nrt + P_S(n) + W(n))$, free steal attempts is $O(PE_m + Pmrt + nrt)$, and trapped steal attempts is $O(T_H + W(n) + nrt + P_S(n) + P_{S^*}(n))$. The total batch-setup overhead is $O(T_H + W(n) + nrt + P_S(n) + P_{S^*}(n))$. Adding the total work and dividing by $P$ gives the result. □

We can now set an appropriate value for $\tau$ to get the bound on BATCHER performance. This corollary is equivalent to Theorem 1.

Corollary 14. BATCHER executes the program described in Theorem 3 in expected time $O\left(\frac{T_H + W(n) + nrt}{P} + ms(n) + T_m\right)$.

Proof. We get this bound by setting $\tau$ to be equal to the data structure span $s(n)$. Recall that long batches are defined as batches with batch span longer than $\tau$, and $\tau$-trimmed span $S_C(\tau)$ is defined as the sum of the spans of all long batches. Recall, also, from the definition of the data-structure span $s(n)$ is defined as follows: For any sequence of batches comprising a total of $n$ data structure nodes, such that no batch contains more than $P$ data structure nodes, $s(n)$ is the worst case span of any batch individual $A$ that also has parallelism limited by $w_A/s_A = O(P)$.

Since the program has a total of $n$ data-structure nodes, and BATCHER only generates batches with at most $P$ data structure nodes, the only batches with $w_A/s_A = s(n)$ are those where $w_A/s_A = \Omega(P)$. Now, say $L$ is the set of long batches. For all $A \in L$, we have $w_A = \Omega(P_{S^*})$, since all other batches have span smaller than $s(n)$, hence also smaller than $\tau$, since $s(n) = \tau$. That is, the long batches are all batches with large parallelism. Therefore, $W(n) \geq \sum_{A \in L} w_A = \sum_{A \in L} \Omega(P_{S^*})$. Since $S_C(\tau) = \sum_{A \in L} s_A$, we conclude that $W(n) = \Omega(P_{S^*}(n))$, or $W(n)/P = \Omega(S_C(\tau))$. The bound follows from Theorem 3 as $W(n)/P$ dominates $S_C(\tau)$. □

6. RELATED WORK

BATCHER most closely resembles various software combining techniques, designed primarily to reduce concurrency overhead in concurrent data structures. In some combining techniques [15, 21, 31], each processor inserts a request in a shared queue and a single processor sequentially executes all outstanding requests later. These works provide empirical efficiency, but we are not aware of any theory bounding the running time of an algorithm using these combiners. BATCHER improves upon these techniques by operating on the “request queue” in parallel and by providing runtime theory. Other software-combining techniques include (static) combining trees [20] or (dynamic) combining funnels [38] which apply directly to data structures with combinable operations like lock objects, counters, or stacks. These do have a provably $O(\log P)$ overhead, but do not address more general structures.

Several related mechanisms designed for dynamic multithreading have a grounding in theory. Reducers [17] in Cilk can be used to eliminate contention on some shared global variables, but are not designed to replace a generic concurrent data structure, since they create local views on each processor rather than maintain a single global view. It is also unclear how to analyze reducers that include highly variable amortized costs. Helper locks [1] provide a mechanism that allows blocked workers to help complete the critical section that is blocking them and is not specifically designed for data structures. Conceptually, one can use this mechanism to execute batches; however, directly applying the analysis of [1] leads to worse completion time bounds compared to using BATCHER.

Concurrency data structures themselves are widely studied [24]. Most theoretical work on concurrent data structures focuses on correctness and forward-progress guarantees like linearizability [25], lock freedom [23], or wait freedom [22]. While wait-free structures often include a worst-case performance bound, the bound may not be satisfying when applied in the context of an enclosing algorithm. For example, a universal wait-free construction of [9] has a worst-case cost that includes a factor of $P$, the number of processors, which implies serializing all data structure operations. Experimental studies of various concurrent B-tree data structures alone spans over 30 years of research [3, 4, 27, 7]. These results typically fall short of bounds on running time, with [4] being one exception assuming uniformly random accesses.

Several batched search trees exist, including 2-3 trees [33], weight-balanced B-trees [14], and red-black trees [16]. Moreover, some of these data structures [14, 16] exhibit good practical performance.

7. EXPERIMENTAL EVALUATION

We implemented a prototype of BATCHER within the Cilk-5 [19] runtime system. Our preliminary evaluation, presented here, is based around a skip-list data structure. Note that the primary contribution of this paper is the theory; these experiments are meant to be only proof of concept, not a comprehensive study. Nevertheless, the results indicate that implicit batching is a promising direction, at least for expensive data structures and large-enough batches. For the particular experiment here, BATCHER’s performance on 1 processor is comparable to that of a sequential skip list, and hence the overhead is not prohibitive. In addition, BATCHER provides speedup when running on multiple processors.

We conducted experiments on a 2-socket machine with 8 cores per socket running Ubuntu 12.04. The processor was Intel Xeon E5-2687W. The machine has 64GB of RAM and 20MB of L3 cache per socket. For our experiments, we pinned the threads to a single socket on this machine.

BATCHER and skip-list implementations. We implemented the BATCHER scheduler by modifying the Cilk-5 runtime system, essentially as described in Section 4. The main difference between the theoretical and the practical design is within the LAUNCHBATCH operation (Figure 4). Because we are running on only 8 cores, we used a sequential implementation for the status changes status changes (lines 1 and 4) and the compaction (line 2).

Our batch insert (BOP) into the skip list has three steps. 1) build a new skip from a set of records, 2) perform searches for these nodes in the main skip list, and 3) splice the new list into the main list. Since the new list is small (batch size), we perform steps 1 and 3 sequentially, whereas the searches into the large main list in step 2 are performed in parallel. The core program is simply a
parallel-for loop that inserts into the skip list in each iteration (e.g., as in Figure 1). Note that this is a bad case for BATCHER since all of the work happens within the data structure, and hence the overheads are tested.

Experimental scaling. In all our experiments, we first initialize the skip list with an initial size. We then timed the insertion of 100,000 additional elements into this skip list. To simulate bigger batches without the NUMA effects of going to multiple sockets, each BATCHIFY call creates 100 insertion records. We compared BATCHER with a sequential implementation where all 100,000 elements are inserted sequentially (without concurrency control).

Figure 5 shows the throughput of BATCHER and a sequential skip list with initialSize 20,000, 100,000, 1 million, 10 million and 100 million (e.g., BAT720000 shows BATCHER’s with initial size 20,000). For initial size 20,000 and 100,000, SEQ performs better than BAT on a single processor. This is because inserts into small skip lists are so cheap that BATCHER’s overheads begin to dominate. However, even on these small skip lists, BATCHER provides speedup, and outperforms the sequential skip list on multiple processors. For larger skip lists, the inserts get expensive enough that they dominate BATCHER’s overhead, and BATCHER performs comparably with the sequential list even on 1 processor.

More interestingly, BATCHER’s speedup increases as the skip list gets larger. At size 100 million, BATCHER provides a speedup of about 3× on 6 processors, and 3.33× on 8 workers.

Figure 5: Throughput of BATCHER and sequential skip list insertion for various initial sizes of skip lists (higher is better).

Flat combining. We view flat combining [21] as a special case of implicit batching where batches execute sequentially. They show that flat combining significantly outperforms a good concurrent skip list, at least for certain workloads, validating the idea of implicit batching. On our experiments, flat combining and BATCHER perform similarly 1 processor. However, the performance of flat combining decreases with increasing cores (their experiments also show this). In contrast, the prototype BATCHER implementation shows speedup.

8. CONCLUSIONS AND FUTURE WORK

BATCHER scheduler is provably efficient, and preliminary experiments indicate that it could provide speedup in practice, especially when data structure operations are expensive enough to amortize the overheads. There are several open questions remaining. Is it possible to remove or reduce the $O(\log P)$ overhead by using a more clever communication mechanism? What data structures are easily and efficiently expressible by this batch mechanism? Does BATCHER improve the performance of real parallel programs? Finally, although BATCHER is designed with work-stealing in mind, note that it may also be applicable to pthreaded programs that use data structures. A pthreaded program could run as normal, with data-structure calls replaced by BATCHER calls allowing work-stealing to operate over the data structure batches while static threading operates over the main program.
