ABSTRACT
Gradient Boosted Regression Stumps (GBRS) is the current state-of-the-art learning paradigm for machine learned web-search ranking — a domain notorious for very large data sets. In this paper, we propose a novel method for parallelizing the training of GBRS. Our technique parallelizes the construction of the individual decision stumps and works using the master-worker paradigm as follows. The data is partitioned among the workers. At each iteration, the worker summarizes its data-partition using histograms. The master processor uses these to build one layer of a decision stump, and then sends this layer to the workers, allowing the workers to build histograms for the next layer. Our algorithm carefully orchestrates overlap between communication and computation in order to get good performance.

Since this approach is based on data partitioning, and requires a small amount of communication, it generalizes to distributed and shared memory machines, as well as clouds. We present experimental results on both shared memory machines and clusters for two large scale web search ranking data sets. We demonstrate that the loss in accuracy induced due to the approximation in the regression stump creation can be compensated for through slightly deeper trees. As a result, we see no significant loss in accuracy on the Yahoo data sets and a very small reduction in accuracy for the Microsoft LETOR data. In addition, on shared memory machines, we obtain almost perfect linear speed-up with up to about 48 cores on the large data sets, on which one can reasonably expect even higher speedups.

1. INTRODUCTION
The last two decades have witnessed the rise of the world wide web from an initial experiment at CERN to a global phenomenon. In this time, web search engines have come to play an important role in how users access the internet, and have seen tremendous advances. A crucial part of a search engine is the ranking function, which orders the retrieved documents according to decreasing relevance to the query.

Recently, web search ranking has been recognized as a supervised machine learning problem [7, 31], where each query-document pair is represented by a high-dimensional feature vector and its label indicates the document’s degree of relevance to the query. During the past few years — fueled through the publication of real-world data sets from large corporate search engines [20, 28] — machine learned web search ranking has become one of the great success stories of machine learning.

Researchers around the world have explored many different learning paradigms for web-search ranking data, including Neural Networks [7], Support Vector Machines [17], Random Forests [4, 21] and gradient boosted regression trees [31]. Amongst these various approaches, gradient boosted regression trees (or stumps) (GBRS) arguably define the current state-of-the-art: In the Yahoo Labs Learning to Rank Challenge 2010, the largest web-search ranking competition to date, all eight winning teams (out of a total of 1055) used approaches that incorporated GBRS. GBRS work by building an ensemble of regression stumps (trees of limited depth). During each iteration a new stump is added to the ensemble, minimizing a pre-defined cost function.

Due to the increasing amount of available data and the ubiquity of multicores and clouds, there is increasing interest in parallelizing machine learning algorithms. Most prior work on parallelizing boosting [18, 29] is agnostic to the choice of the weak learner. In this paper, we take the opposite approach and parallelize the construction of individual weak learners, i.e., the stumps. Our algorithm is inspired by Ben-Haim and Tom-Tov’s work on parallel construction of decision trees for classification [2].
In our approach, the algorithm works step by step constructing one layer of the decision stump at a time. One processor is designated the master processor and the others are the workers. The data is partitioned among the workers. At each step, the workers compress their portion of the data into small histograms and send these histograms to the master. The master approximates the splits using these histograms and computes the next layer in the decision stump. It then communicates this layer to the workers, which allows them to compute the histograms for the subsequent layer construction. The construction stops when a predefined depth is reached.

This master-worker approach with bounded communication has several advantages. First, it can be generalized to multicore, shared memory machines, clusters and clouds with relatively little effort. Second, the data is partitioned among workers and each worker only accesses its own partition of the data. As the size of the data sets increases, it will become impossible for a single worker to hold all of the data in its memory. Therefore, data partitioning is imperative for performance, especially on clusters and clouds.

While adapted from [2], where they use a similar approach for classification trees, this approach is a natural fit for gradient boosting for two reasons. First, the communication between processors at each step is proportional to the number of leaves in the current layer. Therefore, it grows exponentially with the tree depth, which can be a significant drawback for full decision trees. However, since regression stumps used for boosting are naturally very small, this approach works well. Second, the small inaccuracies caused by the tree approximations can be compensated for through marginally deeper stumps (which are still much too small for inter-processor communication to have a noticeable effect) or a relatively small increase in the number of boosting iterations.

In this paper we make several novel contributions: 1. We adapt the histogram algorithms from Ben-Haim and Tomov [2] from their original classification settings to squared-loss regression; 2. We incorporate this histogram-based feature compression into gradient boosted regression trees and derive a novel parallel boosting algorithm; 3. We demonstrate on real-world web-search ranking data that our parallelized framework leads to linear speed-up with increasing number of processors. Our experiments show no significant decrease in accuracy for the Yahoo Learning to rank competition (2010). In particular, on Set 1 (the larger data set), our parallel algorithm, within a matter of hours, achieves Expected Reciprocal Rank results that are within 1.4% of the best known results [6]. On the Microsoft LETOR data set, we see a small decrease in accuracy, but the speed-ups are even more impressive on this data.

To our knowledge, we are the first paper to explicitly parallelize CART [5] stump construction for the purpose of gradient boosting. In addition, most previous work on tree parallelization, which parallelizes tree construction by features or by sub-trees [25], shows speedup of about 4 or 8. In contrast, our approach provides speed-up (on limited depth stumps) of up to 40 on shared memory machines and up to 25 on distributed memory machines. Moreover, our approach is scalable to larger data sets and we expect even better speedups as the data set size increases.

This paper is organized as follows. In section 2, we introduce necessary notation and explain the general setup of machine learned web search ranking. Section 3 reviews gradient boosted regression trees and the greedy CART algorithm for tree construction. Section 4 shows that histograms can be used to approximate the exact splits of regression trees and introduces our parallel version of gradient boosted regression stumps. Section 5 provides the empirical results for speedup and accuracy of our algorithm on several real-world web search ranking data sets. We relate our contribution to previous work in section 6 and conclude in section 7.

2. WEB SEARCH RANKING

Web ranking data consists of a set of web documents and queries. Each query-document pair is represented with a set of features which are generated using properties of both the query and the document. In addition, each pair is labeled, which indicates how relevant the document is to the query. Using this data, the goal is to learn a regressor so that given a new query, we can return the most relevant documents in decreasing order to relevance. In this paper, our algorithmic setup is not affected by the number of queries. Therefore, to simplify notation, we assume that all documents belong to a single query throughout the following sections. However, the techniques work for sets with multiple queries, and in fact, the data we use for experiments does contain many queries.

More formally, we assume that the data is in the form of instances \( D = \{ (x_i, y_i) \} \) consisting of documents \( x_i \in \mathcal{R}^f \) and labels \( y_i \in \{0, 1, 2, 3, 4\} \). A label indicates how relevant document \( x_i \) is to its query, ranging from “irrelevant” (if \( y = 0 \)) to “perfect match” (if \( y = 4 \)). A document is represented by an \( f \) dimensional vector consisting of features that are computed from the document and the query. Our goal is to learn a regressor \( h : \mathcal{R}^f \rightarrow \mathcal{R} \) such that \( h(x_i) \approx y_i \). At test time, the search engine ranks the documents \( \{x_j\}_{j=1}^m \) of a new query in decreasing order of their predicted relevance \( \{h(x_j)\}_{j=1}^m \).

The quality of a particular predictor \( h(\cdot) \) is measured by specialized ranking metrics. Most commonly used metrics are Expected Reciprocal Rank (ERR) [9], which is meant to mimic user behavior, and Normalized Discounted Cumulative Gain (NDCG) [16], which emphasizes leading results (NDCG). However, these metrics can be non-convex, non-differentiable or even non-continuous. Although some recent work [30, 26, 10] has focused on optimizing these ranking metrics directly, the more common approach is to optimize a well-behaved surrogate cost function \( \mathcal{C}(h) \) instead, assuming that this cost function mimics the behavior of these other metrics.

In general, the cost functions \( \mathcal{C} \) can be put into three categories of ranking: pointwise [13], pairwise [15, 31] and listwise [8]. In pointwise settings the regressor attempts to approximate the label \( y_i \) of a document \( x_i \) directly, i.e. \( h(x_i) \approx y_i \). A typical loss function is the squared-loss

\[
\mathcal{C}(\mathcal{h}) = \sum_{i=1}^{n} (h(x_i) - y_i)^2. 
\]

The pairwise setting is a relaxation of pointwise functions, where pairs of points are considered. It is no longer important to approximate each relevance score exactly, rather the partial order of any two documents should be preserved. An example is the cost function of GBRANK [31],

\[
\mathcal{C}(\mathcal{h}) = \sum_{(i,j) \in \mathcal{P}} \max(0, 1 - (h(x_i) - h(x_j))^2),
\]

where \( \mathcal{P} \) is the set of all possible pairings of documents.
where \( \mathcal{P} \) is the preference set of all document pairs \((i, j)\) belonging to the same query, where \( i \) should be preferred over \( j \). Listwise approaches [8] are similar to the pairwise approach, but focus on all the documents that belong to a particular query and tend to have slightly more complicated cost functions. Recent research [10] also focused on breaking the ranking problem into multiple binary classification tasks.

In this paper, we do not restrict ourselves to any particular cost function. Instead we assume that we are provided with a generic cost function \( C() \), which is continuous, convex and at least once differentiable.

### 3. BACKGROUND

In this section we first review Gradient Boosting [13] as a general meta-learning algorithm for function approximation and then remind the reader of regression trees [5].

#### Gradient Boosting

Gradient Boosting [13] is an iterative algorithm to find an additive predictor \( h(\cdot) \in \mathcal{H} \), that minimizes \( C(h) \). At each iteration \( t \), a new function \( g_t(\cdot) \) is added to current predictor \( h_t(\cdot) \), such that after \( T \) iterations, \( h_T(\cdot) = \alpha \sum_{t=1}^{T} g_t(\cdot) \), where \( \alpha > 0 \) is some non-negative learning rate. At each iteration \( t \), \( g_t(\cdot) \) is chosen as an approximate of the negative derivative in function space, \( g_t(\cdot) \approx -\frac{\partial C}{\partial h_t} \).

In order to find an appropriate function \( g_t(\cdot) \) in each iteration \( t \), we assume the existence of an oracle \( \mathcal{O} \). For a given function class \( \mathcal{H} \) and a set \( \{(x_i, r_i)\} \) of document and target pairs, this oracle returns the function \( g \in \mathcal{H} \) that best approximates the response values according to the squared loss function \( C(\cdot) = \sum_{i=1}^{n} (g(x_i) - r_i)^2 \).

In iteration \( t \), gradient boosting attempts to find the function \( g(\cdot) \) such that \( C(h_t + g) \) is minimized. Let us approximate the inner-product between two functions \((f(\cdot), g(\cdot))\) as \( \sum_{i=1}^{n} f(x_i)g(x_i) \). By the first-order Taylor Expansion, we obtain

\[
g \approx \arg\min_{g \in \mathcal{H}} \Bigg[ C(h_t) + \sum_{i=1}^{n} \frac{\partial C}{\partial h_t(x_i)} g(x_i) \Bigg]. \tag{4}
\]

If we assume that the norm of \( g \in \mathcal{H} \) is constant, \(^2\) i.e., \( \langle g, g \rangle = c \), the solution of the minimization (4) becomes \( \mathcal{O}(\{(x_i, r_i)\}) \), where \( r_i = -\frac{\partial C}{h_t(x_i)} \). This follows from a simple binomial expansion of (3), where the two quadratic terms are constants and therefore independent of \( g \). In the case where \( C() \) is the squared-loss from (1), the assignment becomes the current residual \( r_i = y_i - h_t(i) \). Algorithm 1 summarizes gradient boosted regression in pseudo-code.

In web-search ranking, and other domains, the most successful choice for the oracle in (3) is the greedy Classification and Regression Tree (CART) algorithm [5] with limited depth size \( d \) between 4 and 5. Due to their small size, these limited-depth trees are usually referred to as regression stumps. This paper focuses exclusively on the parallelization of Gradient Boosted Regression Stumps (GBRS). We review the basic CART algorithm in the following section.

#### Regression Stumps

Regression stump construction in CART [5] proceeds by repeated greedy expansion of nodes until a stopping criterion, e.g. tree depth, is met. Initially, all data points are assigned to a single node, the root of the tree. To simplify notation, we explain the algorithm for data with one single feature and only drop the feature indices (e.g. \( x \) is the feature value for input \( i \)). In practice, the same steps are performed for all features, and the feature that leads to the split with the maximum reduction in cost is chosen. At each node, with data \( S \subseteq D \), the prediction made by the classifier is the average label in \( S \). Let denote this predictor as \( \bar{y}_S = \frac{1}{|S|} \sum_{(x_i, y_i) \in S} y_i \). It is straightforward to show that \( y_s \) minimizes the loss of a constant predictor over a set \( S \):

\[
\bar{y}_S = \arg\min_p \sum_{i \in S} (y_i - p)^2. \tag{5}
\]

At each step, the data \( S \subseteq D \) assigned to each leaf node is partitioned into two subsets \( L, R \subseteq S \) by splitting on a feature value \( s \). We define the two subsets \( L^* = \{(x_i, y_i) \in S \mid x_i < s \} \) and \( R^* = S - L^* \). Let \( j_1, \ldots, j_{|S|} \) be the indices of the ordered set \( S \) such that \( y_{j_1} \leq y_{j_2} \leq \ldots \). Therefore, we have \(|S|\) potential split points, one between each consecutive elements. The optimal value \( s^* \) is found by iterating over all these possible split values \( P \) and evaluating the accumulative squared loss on both sides of the tree:

\[
s^* = \arg\min_{p \in P} \sum_{i \in L^*} (y_i - \bar{y}_L) + \sum_{i \in R^*} (y_i - \bar{y}_R) \tag{6}
\]

where:

\[
P = \left\{ \frac{y_{j_{i+1}} - y_{j_i}}{2} \mid 1 \leq i < |S| \right\}
\]

Eq. (6) can be solved in \( O(n) \) time through dynamic programming [5]. However, the dynamic programming approach requires the samples to be sorted, which in itself requires \( O(n \log(n)) \) operations.

### 4. PARALLEL IMPLEMENTATION

In this section, we describe our approach for parallelizing the construction of gradient boosted regression stumps. In this approach, the boosting still occurs sequentially, as we parallelize the construction of individual tree stumps. Two key insights enable our parallelization. First, in order to evaluate a potential split point during stump construction we only need cumulative statistics about all data left and right of the split, but not these data themselves. Second,
Algorithm 2 Parallel CART Master

Parameter: maximum depth
tree ← unlabeled node
while tree depth < maximum depth do
  for each feature f do
    instantiate an empty histogram at each leaf
  end for
  for each worker do
    initiate non-blocking receive for worker’s histograms
  end for
  while ∃ non-completed receives do
    wait for some receive to complete
    merge received histograms with histograms at leaves
  end while
  update best splits for each leaf
  send next layer of leaves to each worker
end while

Algorithm 3 Parallel CART Worker

Input: data set \( D = \{(x_i, r_i)\}_{i=1}^n \)
Parameter: maximum depth
tree ← unlabeled node
while tree depth < maximum depth do
  navigate training data \( D \) to leaf nodes \( v \)
  for each feature \( f \) do
    instantiate an empty histogram \( h_v \) for each leaf \( v \)
    for \((x_i, r_i) \in D \) at leaf \( v \) do
      merge(\( h_v, (\{|x_i, 1, r_i\}|) \))
    end for
    initiate non-blocking send for histograms from all leaves
  end for
  receive next layer of leaves from master
end while

boosting does not require the weak learners to be particularly accurate. A small reduction in accuracy of the decision stumps can potentially be compensated for by using more decision stumps without affecting the accuracy of the boosted classifier.

In our algorithm, we have a master processor and \( P \) workers. We assume that the data are divided into \( P \) disjoint subsets stored in different physical locations and each worker can access one of these locations. Let \( D_p \) be the set of data instances stored at site \( p \), so that \( \bigcup_{p=1}^P D_p = D \) and \( D_p \cap D_q = \emptyset \) for \( p \neq q \) and \( |D_p| = |D|/P \). The master processor builds the decision stumps layer by layer. At each iteration, a new layer is constructed as follows: Each worker compresses its subsets stored in different physical locations and each worker

\begin{algorithm}
\caption{Parallel CART Worker}
\begin{algorithmic}
\State \textbf{Input:} data set \( D = \{(x_i, r_i)\}_{i=1}^n \)
\State Parameter: maximum depth
\State \textbf{tree} ← unlabeled node
\While {tree depth < maximum depth}
  \For {each feature \textbf{f}}
    \State instantiate an empty histogram \( h_v \) for each leaf \( v \)
  \EndFor
  \For {(\(x_i, r_i) \in D \)} at leaf \( v \)
    \State merge(\( h_v, (\{|x_i, 1, r_i\}|) \))
  \EndFor
  \For {each \textbf{worker}}
    \State initiate non-blocking receive for histograms from all leaves
  \EndFor
  \State receive next layer of leaves from master
\EndWhile
\end{algorithmic}
\end{algorithm}

\begin{algorithm}
\caption{Parallel CART Master}
\begin{algorithmic}
\State Parameter: maximum depth
\State \textbf{tree} ← unlabeled node
\While {tree depth < maximum depth}
  \For {each feature \textbf{f}}
    \State instantiate an empty histogram at each leaf
  \EndFor
  \For {each \textbf{worker}}
    \State initiate non-blocking receive for worker’s histograms
  \EndFor
  \While {∃ non-completed receives}
    \State wait for some receive to complete
    \State merge received histograms with histograms at leaves
  \EndWhile
  \State update best splits for each leaf
  \State send next layer of leaves to each worker
\EndWhile
\end{algorithmic}
\end{algorithm}

we lack discrete labels since we are working in a regression setting, so we cannot have different histograms for each label. Instead, our histograms contain triples, \((p_j, m_j, r_j)\), where each triple \((p_j, m_j, r_j)\) summarizes a bin \( B_j \subset S \) containing \( m_j = |B_j| \) inputs around a center \( p_j = \frac{1}{m_j} \sum_{x_i \in B_j} x_i \). In the original algorithm, as described in [2], each processor summarizes its data by generating one histogram per label.

We now explain this algorithm using three steps: First, we identify cumulative statistics that are sufficient to train a regression stump over a data set. Second, we describe how we can construct histograms with a single pass over the data and use them to approximate the cumulative statistics and the best split. Finally, we describe the algorithms that run on the master and workers and how we overlap computation and communication to achieve good parallel performance.

### Cumulative statistics

We wish to evaluate (6) with cumulative statistics about the data set. Consider the setting from Section 3. A data set \( S \) is split along a feature value \( s \) into \( L_s^+, R_s^+ \subseteq S \). Let \( \ell_s \) denote the sum of all labels and \( m_s \) the number of inputs within \( L_s^+ \):

\[
\ell_s = \sum_{i,x_i \in L_s^+} y_i \quad \text{and} \quad m_s = |L_s^+|.
\]  

With this notation, the predictors \( \tilde{y}_L^+, \tilde{y}_R^+ \) for the left and right subset can be expressed as

\[
\tilde{y}_L = \frac{\ell_s}{m_s} \quad \text{and} \quad \tilde{y}_R = \frac{\ell_{s - \ell_s}}{m_s - m_s}.
\]  

Expanding the squares in (6) and substituting into it the definitions from (7) and (8) allows us to write the optimization to find the best splitting value \( s^* \) entirely in terms of the cumulative statistics \( \ell_s \) and \( m_s \):

\[
\ell_s^2 - \ell_{s - \ell_s}^2 \quad \text{and} \quad \ell_{s - \ell_s}^2.
\]  

Since \( \ell_{s} \) and \( m_{s} \) are constants, in order to evaluate a split point \( s \), we only require the values of \( \ell_s \) and \( m_s \).

### Histograms

The traditional GBRS algorithm, as described in Section 3, spends the majority of its computation time evaluating split points during the creation of regression stumps. We speed up and parallelize this process by summarizing label and feature-value distributions using histograms. Here we describe how a single split, evaluated on the data that reaches that particular node, is computed using these histograms.

Ben-Haim and Tom-Tov [2] introduced a parallel histogram based decision tree algorithm for classification. A histogram \( h \), over a data set \( S \), is a set of tuples \( h = \{(p_1, m_1), ..., (p_n, m_n)\} \), where each tuple \((p_j, m_j)\) summarizes a bin \( B_j \subset S \) containing \( m_j = |B_j| \) inputs around a center \( p_j = \frac{1}{m_j} \sum_{x_i \in B_j} x_i \). In the original algorithm, as described in [2], each processor summarizes its data by generating one histogram per label.

We lack discrete labels since we are working in a regression setting, so we cannot have different histograms for each label. Instead, our histograms contain triples, \((p_j, m_j, r_j)\), where \( r_j = \sum_{x_i \in B_j} y_i \) is the cumulative document relevance of the \( j \)th bin. Recall that for simplicity in explanation, we are assuming that there is a single feature in the data. In reality, both classification and regression approaches generate different histograms for each feature.

**Construction:** A histogram \( h \) can be built over a data set \( S \) in a single pass. For each input \((x_i, y_i) \in S \), a new bin \((x_i, 1, y_i)\) is added to the histogram. If the size of the histogram exceeds a predefined maximum value \( b \) then the two nearest bins are merged. The nearest bins

\[
i, j = \text{argmin}_{i', j'} |x_{i'} - x_{j'}|
\]  

are replaced by a single bin:

\[
\left( \frac{m_i p_i + m_j p_j}{m_i + m_j}, m_i + m_j, r_i + r_j \right).
\]  

...
Once the workers send all their respective histograms to the master, the master merges them by applying the same merging rule, i.e., merging bins of one histogram into another one by one.

**Interpolation:** Given the compressed information from the merged histogram $h = \{(p_j, m_j, r_j)\}_{j=1}^n$, we need to approximate the values of $m_s$ and $\ell_s$ to find the best split point $s^*$, as defined in (9). Let us first consider the case where $s = p_j$ for some $1 < j < b$, i.e., we are evaluating a split exactly at a centroid of a bin. To approximate the values of $m_{p_j}$ and $\ell_{p_j}$, we assume that the number of points and relevances are evenly distributed around the mean $p_j$.

In other words, half of the points $m_j$ and half of the total relevance $r_j$ lies on the left side of $p_j$. The approximations then become:

$$m_{p_j} \approx \frac{j-1}{2} \sum_{k=1}^{j} m_k + \frac{m_j}{2} \quad \text{and} \quad \ell_{p_j} \approx \frac{j-1}{2} r_k + \frac{r_j}{2}. \quad (12)$$

If a potential splitting point $s$ is not at the center of a bin, i.e., $p_i < s < p_{i+1}$, we interpolate the values of $m_s$ and $\ell_s$.

Let us consider $\ell_s$ first. As we already have $\ell_{p_i}$, all we need to compute is the remaining relevance $\Delta = \ell_{p_{i+1}} - \ell_{p_i} = \sum_{p_i \leq s < p_{i+1}} r_i$, such that $\ell_s = \ell_{p_i} + \Delta$. If we follow our assumption that the points around bins $i$ and $i+1$ are evenly distributed, then there is a total relevance of $R = \frac{r_i + r_{i+1}}{2}$ within the bin centers $p_i$ and $p_{i+1}$. We assume that this total relevance is evenly distributed within the area under the histogram curve between $[p_i, p_{i+1}]$. Let $a(s) = a_r(s) R_i$, be the area under the curve within $[p_i, s]$. The sum of relevance within $[p_i, s]$ is then proportional to $a(s)/a(p_{i+1})$. We use the trapezoid method to approximate the integral $a(s)$ and interpolate $\ell_s$ with

$$\ell_s = \ell_{p_i} + \frac{a_r(s)}{a_r(p_{i+1})} R_i \quad \text{where:}$$

$$a_r(s) \approx \frac{(r_i + r_s)(s - p_i)}{2} \quad \text{and} \quad r_s = \frac{r_{i+1} - r_i}{p_{i+1} - p_i} (s - p_i).$$

The interpolation of $m_s$ is analogous to (13), except that all $r_s$ are substituted for $m_s$. Now we can interpolate cumulative statistics $\ell_s$ and $m_s$ from histograms for arbitrary split points $s$, there are potentially infinite number of candidate split points. We select the set of candidate split points $\{s_i\}$ positioned uniformly on the distribution of $x \in S$. These uniformly distributed points may be estimated by the Uniform procedure described in [2].

The use of histograms (even on a single cpu) speeds up the GBRS training time significantly, as it alleviates the need to sort the features to identify all possible split points. The time complexity for tree construction reduces from $O(n \log(n))$ to $O(n \log(b))$, where $b \ll n$.

**Distributed GBRS**

In addition to an inherent speedup in tree construction, histograms allow the construction of regression stumps to proceed in parallel. Worker nodes compress distributed subsets of the data into small histograms. These, when merged, represent an approximate, compressed view of an entire data set, and can be used to compute the split points. We now explain our distributed algorithm in more detail. We also no longer assume that there is a single feature in order to explain the algorithm more completely.

A layout in pseudo-code for the master and worker are depicted in Algorithms 2 and 3. As mentioned above, the data is partitioned into $P$ sets, one for each worker. The workers are responsible for constructing histograms and the master is responsible for merging the histograms from all workers finding the best split points. At each step, the master finds the best split for all the current leaf nodes, generating a new layer of leaves, and sends this new layer to the workers. The workers first evaluate each data point in their partition and navigate it to the correct leaf node. They then create an empty histogram per feature per leaf. They summarize their respective data partition in these histograms (using the histogram construction algorithm described above) and send them to the master. The master merges these histograms to split the leaves again. Initially, the tree consists of a single root node.

The number of histograms generated per iteration is proportional to the number of features times the number of leaves $O(f \times 2^d)$ (where $d$ is the current depth of the tree). As $d$ increases, this communication requirement may become significant and overwhelm the gains made from parallelization. However, for small depth stumps and sufficiently large data sets, we achieve drastic speedups since the majority of computation time is spent by the workers in compressing the data. In addition, notice that the number of histograms does not depend on the size of the data set, and therefore, the algorithm is scalable as the size of the data increases. Further, communication volume is tunable by the compression parameter $b$ which sets the maximum number of bins in each histogram. At a possible sacrifice of accuracy, smaller histograms may be used to limit communication.

When using such master/worker message passing algorithms, it is important to consider two objectives in order to get good performance. First, the computation and communication should be overlapped so processors don’t block on communication. Second, the number of messages sent should not be excessive since initializing communication carries some fixed cost. Our algorithm is designed to carefully balance these two objectives. In order to overlap computation and communication, the workers compute the histograms feature by feature and send these histograms to the master while they move on to the next feature. In order to allow this with just one pass over the data, we store our data feature wise, that is, the values of a particular feature for all instances are stored contiguously. To avoid generating unnecessarily small messages, all the histograms corresponding to a particular feature, across all leaves, are sent as a single message. That is, instead of sending one message per histogram, the worker generates one message per feature. Therefore, the number of messages does not increase with the depth even though the size of messages does increase.

5. EXPERIMENTAL RESULTS

In this section, we describe the empirical evaluation of our algorithm using several publicly available web search ranking data compilations. We see impressive speedups on both shared memory and distributed memory machines. In addition, we found that, while individual decision stumps are weaker using our approximate parallel algorithm (as ex-

Table 1 summarizes statistics about all data set collections.

For all experiments, for simplicity, we used the squared-loss as our cost-function $C(\cdot)$. Our algorithm has four parameters: The depth of the decision stumps $d$, the number of boosting iterations $m$, the step-size $\alpha$ and the number of bins $b$ in the histograms. We perform most experiments on the sensitivity of these parameters only on the Yahoo Set 1 and 2, as these span two different ranges of data set sizes (Set 1 is almost one order of magnitude larger than Set 2).

**Prediction Accuracy:** As a first step, we investigate how much the ranking performance, measured in NDCG [16] and ERR [9], is impacted by the approximated construction of the regression stumps.

Figure 1 shows the NDCG and ERR of the parallel implementation “pGBRS” and of the exact algorithm “GBRS” as a function of the number of boosting iterations on the Yahoo Set 1 and 2 under varying tree depths. For the parallel implementation, we used $b = 25$ bins for Set 2 and $b = 50$ for the much larger Set 1. The step-size was set to $\alpha = 0.06$ in both cases.

As expected, the histogram approximation reduces the accuracy of the weak learners. Consequently, with equal depth and iterations, pGBRS has lower ERR and NDCG than the exact GBRS. However, we can compensate for this effect by either running additional iterations or increasing the depth of the decision stumps. In fact, it is remarkable that on Set 1 (Figure 1) the NDCG curves of pGBRS with $d = 6$ and $d = 5$ align almost perfectly with the curves of GBRS with $d = 5$ and $d = 4$. For Set 2 the lines are mostly shifted by approximately 200 iterations. The additional computation required by either of these approaches (increasing $d$ or $m$) is more than compensated for by the better performance of the histogram method since it does not require feature sorting.

For small $d \leq 10$ – while the computation is dominated by prediction – the running time increases roughly linearly with increasing $d$. On the Yahoo Set 1, training pGBRS with $m = 6000$ trees on 16 cpus and depth $d = 5$ was only a factor 1.34 slower than $d = 4$ and a depth of $d = 6$ slowed the training time down by a factor of 1.75.

Table 2 shows the test result on all data sets of GBRS with $d = 4$ and pGBRS for $d = 4, 5, 6$ (the number of trees $m$ was picked with the help of the corresponding validation data sets). As the table shows, for all data sets, the difference between pGBRS with $d = 6$ and GBRS with $d = 4$ is in the last (third) significant digit for all data sets. For the two Yahoo data sets, pGBRS provides slightly better accuracy, while for the Microsoft data sets, the exact algorithm is slightly better. The Microsoft data sets were run with

The only large-scale open-source GBRS implementation, with a total of 48 cores). On both machines, we used the same number of RAM each. For our experiments, we used 6 of these nodes computing nodes running at 2.73GHz. They each have 24GB distributed memory cluster consists of 8-core, Nehalem based 1U-A1403 48-core SMP machine with four sockets containing AMD Opteron 6168 Magny-Cours processors. The distributed memory cluster consists of 8-core, Nehalem based computing nodes running at 2.73GHz. They each have 24GB of RAM each. For our experiments, we used 6 of these nodes (with a total of 48 cores). On both machines, we used the same implementation of the algorithm, which uses MPI [24]. We will make the code available under an open source license. We compare against the exact GBRS implementation\(^3\) described in [21], which to our knowledge is currently

\(^3\)http://research.engineering.wustl.edu/~amohan/
parameters ($\alpha = 0.1, b = 100, m \leq 5000$). We increased the number of bins since the data set is larger.

We also evaluated the sensitivity of the algorithm to the number of histogram bins $b$ and the number of processors. Figure 2 shows several runs ($\alpha = 0.05, d = 5$) with varying numbers of histogram bins assessed by quality measures which have been scaled by the best observed accuracy for each measure. For each run we report the best result (in terms of iterations $m$) based on the validation data set. We see that while the prediction accuracy increases slightly as the number of bins increases, it converges quickly at about 15 bins, and the differences thereafter are insignificant. In a similar experiment (not shown) we measured prediction accuracy while varying the number of processors. Despite more histograms being inexactly merged with each additional processor, we did not observe any noticeable drop in accuracy as the number of processors increased.

To demonstrate that our algorithm is competitive with the state-of-the-art, we selected the parameters $m, d, b$ by cross-validation on the validation sets of both Yahoo data sets (for simplicity we fixed $\alpha = 0.06$ as GBRS is known to be relatively insensitive to the step-size). This yielded test set ERR of 0.4614 on Set 1 (step-size $m = 3926, d = 7, b = 100$) and 0.4596 on Set 2 ($m = 3000, d = 5, b = 50$). The ERR score of Set 1 would have placed us 15th (and 14th for Set 2) on the leaderboard of the 2010 Yahoo Learning to Rank Challenge\(^\dagger\) out of a total of 1055 competing teams. This result – despite our simple squared-loss function – is only 1.4% below the top scoring team, which used an ensemble of specialized predictors and fine-tuned cost functions that explicitly approximate the ERR metric [6]. We assume that better scores could be achieved with our parallel algorithm as well by using more specialized loss functions $C(\cdot)$ – however this is beyond the scope of this paper.

Performance and Speedup: For performance measurements, we trained pGBRS for $m = 250$ trees of depth $d = 5$ using histograms with $b = 25$ bins. Figure 3 shows the speedup of our pGBRS algorithm on both the Yahoo and the LETOR Fold 1 while running on the shared memory machine. For the smaller data set (Set 2), we achieve speedup of up to 10 on 13 cores. For the larger data set (Set 1), we achieve much higher speedups, up to 33 on 41 processors, reducing the training time on Set 1 from over 11 hours to merely 21 minutes. On the Microsoft data (almost twice as many samples as Yahoo Set 1), we see the speedup of up to 42 on 48 cores, and there is potential for more speedup on more cores since the line hasn’t plateaued yet. We see more speedup on the Microsoft data since it has fewer features (requires less communication) and more documents (increases the fraction of time spent on tree construction). While Set 1 and LETOR are among the largest publicly available data sets, proprietary data sets are potentially much larger, and we expect further speedup on those.

Figure 4 shows the speedup of our parallel GBRS on both the Yahoo and the LETOR datasets while running on the cluster. As expected, due to the communication latency, the speedup is smaller, and flattens out after 32 cores. How-

\(^\dagger\)http://learningtorankchallenge.yahoo.com/leaderboard.php
ever, we still see the speedup of about 20 on Yahoo Set 1 and about 25 on the LETOR data.\textsuperscript{5} This result demonstrates the generality of our parallelization methods in that the same strategy (and even the same code) can provide impressive speedups on a wide variety of parallel machines.

All speed-up results are reported relative to the sequential pGBRS version (1 helper cpu). We do not report speedup compared to the exact algorithm, since this codebase uses different data structures and timing results might not be representative. In general, however, the speed-up with respect to the 1-cpu pGBRS runs understate the speedup over the exact algorithm, since the exact algorithm available to us is considerably slower than pGBRS, even on a single processor. Just for comparison, sequentially (1 helper cpu), our parallel algorithm completes execution in 3,178 s on Yahoo Set 2 and 43,189 s on Set 1, both with depth 5. Even with a smaller depth 4, the exact GBRS implementation takes 5,940 s on Set 2 and 259,613 s on Set 1. Particularly for Set 1, the exact algorithm is about 6 times slower than the approximate algorithm even when running with a smaller depth.\textsuperscript{6}

6. RELATED WORK

In this section, we present a sample of previous work on parallel machine learning most related to our work. The related work falls into three categories: parallel decision trees, parallelization of boosting, and parallelization of web search ranking using other approaches like bagging.

Parallel decision tree algorithms have been studied for many years, and can be grouped into two main categories: task-parallelism and data-parallelism. Algorithms in the first category\textsuperscript{[11, 25]} divide the tree into sub-trees, which are constructed on different workers, e.g. after the first node is split, the two remaining sub-trees are constructed on separate workers. There are two downsides of this approach. First, each worker should either have a full copy of the data or large amount of data has to be communicated to workers after each split. Therefore, for large data sets, especially if the entire data set doesn’t fit in each workers memory, this scheme would likely provide slowdown rather than speedup. Second, small stumps are unlikely to get much speedup, since they cannot utilize all the available workers. Our algorithm falls into the second approach\textsuperscript{[1]}, data-parallelism, where the training data is divided among the different workers. The data can either be divided up by features\textsuperscript{[12]}, or by samples\textsuperscript{[23]}. Dividing by feature requires the workers to coordinate which input falls into which tree-node, as the individual workers do not have enough information to com-

\textsuperscript{5}We see some performance irregularities (in the form of ziggazas) for the LETOR data set. We are investigating these irregularities and suspect that they are due to caching and memory bandwidth effects.

\textsuperscript{6}Exact implementations with clever bookkeeping\textsuperscript{[14]} may be faster – however, to our knowledge, no large-scale implementations are openly available. We expect, nonetheless, that our algorithm can be optimized to perform, on a single cpu, comparably or faster than optimized exact implementations, since it doesn’t require feature sorting.
Table 2: Results in ERR and NDCG on the Yahoo and Microsoft data sets. The number of boosting iterations is selected with the validation data set. On both Yahoo data set, pGBRS matches the result of GBRS with $d = 4$ when the stump depth is increased. For the Microsoft data sets the ranking results tend to be slightly lower.

compute it locally. This requires $O(n)$ communication, which we try to avoid as we scale to very large data sets. Dividing the data by samples [23] avoids this problem. However, in order to obtain the exact solution, all nodes are required to evaluate the potential split points found by all other nodes. Our approach splits the data by samples, and deliberately only approximates the exact split, making the communication requirement independent of the data set size.

Our algorithm is most similar to Ben-Haim and Tov-Tov’s work on parallel approximate construction of decision trees for classification [2]. Our histogram methods were largely inspired by their publication. However, our approach differs in several ways. First, we use regression trees instead of classification – requiring us to interpolate relevance scores within histogram bins instead of computing one histogram per label. Further, our method explicitly parallelizes gradient boosted regression stumps, using trees with a fixed small depth. The communication required for workers to exchange the feature-histograms grows exponentially with the depth of the tree. In our experiments, for trees with depth $d \geq 15$ (consisting of over 65,535 tree nodes), we saw a slowdown (instead of speedup) due to increased communication. This drastically reduces the benefit of parallelization of full decision or regression trees on large data sets, since the required tree depth grows with increasing data set size. In contrast, our framework deliberately fixes the tree-depth to a small value (e.g. $d$ between 4 and 6 with 63 to 255 tree-nodes). Instead of deeper trees, larger data sets require more boosting iterations, which is not a problem for us. As we show in Section 5 (Figure 3), our pGBRS algorithm obtains more speed-up on larger data sets, as the parallel scan of the data to construct histograms takes up a larger fraction of the overall running time.

Most of the previous work on parallelizing boosting focuses on the original AdaBoost algorithm [18] instead of gradient boosting. MultiBoost [27] combines wagging with AdaBoost, which can be performed in parallel, but inherits AdaBoost’s sensitivity to noise.

Finally, there have been multiple approaches to apply bagging [3] for web-search ranking. Recent work by Pavlov and Brunk [22] uses bagged boosted regression trees. Bagging is inherently parallel but requires additional computation time as it is averaged over many independent runs (the solution of Pavlov and Brunk for the Yahoo Learning to rank Challenge required a total of $M = 300,000$ trees of depth $d = 12$). Usually, the choice between Bagging and Boosting is more a decision based on different learning paradigms rather than computational resources.

7. CONCLUSIONS

We have presented a parallel algorithm for training gradient boosted regression stumps. To our knowledge, this is the first work that explicitly parallels the construction of decision stumps for the purpose of boosting. Our approach utilizes the facts that gradient boosting is known to be robust to the classification accuracy of the weak learners and that regression stumps are of strictly limited depth. We have shown that our approach provides impressive (almost linear) speedups on several large-scale web-search data sets without any significant sacrifice in accuracy.

Our method applies to multicore shared-memory systems as well as to distributed setups in clusters and clouds (e.g. Amazon EC2). The distributed setup makes our method particularly attractive to real-world settings with very large data sets. Since each processor only needs enough physical memory for its partition, and the communication is strictly bounded, this allows the training of machine-learned rankers on web-scale data sets even with standard off-the-shelf computer hardware. Given the current trend towards multicore processors, parallel computing and larger data sets, we expect our algorithm to increase in both relevance and utility in the foreseeable future.

We are planning to extend this work in several directions. First, we think we can further increase the efficiency and performance by eliminating the master and merging histograms pairwise among workers. In addition to freeing the master processor for useful work, this approach would further overlap computation and communication. Second, we are planning to run experiments with more workers on clouds to guage the efficacy of this approach on non-dedicated machines. Third, we are planning to investigate adding even more inaccuracy in the computation of the splits. For example, each worker can construct the histograms for only some of the features (instead of all the features as in the current algorithm). This approach should reduce both the communication requirement and the amount of work done by each worker on each step. If we assume that the data on each processor is uniformly sampled from the complete data set, then this approach should still allow the master to compute split points with reasonable accuracy. Since features
have different prediction quality, however, this approach requires careful tuning of how the workers choose the sample of features they construct histograms for.

8. ACKNOWLEDGEMENTS

We would like to thank Ananth Mohan for sharing his implementation of Gradient Boosted Regression Stumps and Yahoo Labs for providing resources for this research.
