ABSTRACT
An effective approach for energy conservation in wireless sensor networks is scheduling sleep intervals for extraneous nodes, while the remaining nodes stay active to provide continuous service. For the sensor network to operate successfully, the active nodes must maintain both sensing coverage and network connectivity. Furthermore, the network must be able to configure itself to any feasible degrees of coverage and connectivity in order to support different applications and environments with diverse requirements. This paper presents the design and analysis of novel protocols that can dynamically configure a network to achieve guaranteed degrees of coverage and connectivity. This work differs from existing connectivity or coverage maintenance protocols in several key ways: 1) We present a Coverage Configuration Protocol (CCP) that can provide different degrees of coverage requested by applications. This flexibility allows the network to self-configure for a wide range of applications and (possibly dynamic) environments. 2) We provide a geometric analysis of the relationship between coverage and connectivity. This analysis yields key insights for treating coverage and connectivity in a unified framework: this is in sharp contrast to several existing approaches that address the two problems in isolation. 3) Finally, we integrate CCP with SPAN to provide both coverage and connectivity guarantees. We demonstrate the capability of our protocols to provide guaranteed coverage and connectivity configurations, through both geometric analysis and extensive simulations.

1. INTRODUCTION
Energy is a paramount concern in wireless sensor network applications that need to operate for a long time on battery power. For example, habitat monitoring may require continuous operation for months, and monitoring civil structures (e.g., bridges) requires an operational lifetime of several years. Recent research has found that significant energy savings can be achieved by dynamic management of node duty cycles in sensor networks with high node density. In this approach, some nodes are scheduled to sleep (or enter a power saving mode) while the remaining active nodes provide continuous service. A fundamental problem is to minimize the number of nodes that remain active, while still achieving acceptable quality of service for applications. In particular, maintaining sufficient sensing coverage and network connectivity with the active nodes are critical requirements in sensor networks.

Sensing coverage characterizes the monitoring quality provided by a sensor network in a designated region. Different applications require different degrees of sensing coverage. While some applications may only require that every location in a region be monitored by one node, other applications require significantly higher degrees of coverage. For example, distributed detection [15] requires every location be monitored by multiple nodes, and distributed tracking and classification [9] requires even higher degrees of coverage. The coverage requirement also depends on the number of faults that must be tolerated. A network with a higher degree of coverage can maintain acceptable coverage in face of higher rates of node failures. The coverage requirement may also change after a network has been deployed due to changes in application modes or environmental conditions. For example, a surveillance sensor network may initially maintain a low degree of coverage required for distributed detection. After an intruder is detected, however, the region in the vicinity of the intruder must
reconfigure itself to achieve a higher degree of coverage required for distributed tracking.

Sensing is only one responsibility of a sensor network. To operate successfully a sensor network must also provide satisfactory connectivity so that nodes can communicate for data fusion and reporting to base stations. The connectivity of a graph is the minimum number of nodes that must be removed in order to partition the graph into more than one connected component. The active nodes of a sensor network define a graph with links between nodes that can communicate. If this graph is K-connected, then for any possible K-1 active nodes which fail the sensor network will remain connected. Connectivity affects the robustness and achievable throughput of communication in a sensor network.

Most sensor networks must remain connected, i.e., the active nodes should not be partitioned in any configured schedule of node duty cycles. However, single connectivity is not sufficient for many sensor networks because a single failure could disconnect the network. At a minimum, redundant potential connectivity through the inactive nodes can allow a sensor network to heal after a fault that reduces its connectivity, by activating particular inactive nodes. Alternatively, transient communication disruption can be avoided by maintaining greater connectivity among active nodes. Greater connectivity may also be necessary to maintain good throughput by avoiding communication bottlenecks.

Although achieving energy conservation by scheduling nodes to sleep is not a new approach, none of the existing protocols satisfy the complete set of requirements in sensor networks. First, most existing solutions have treated the problems of sensing coverage and network connectivity separately. The problem of sensing coverage has been investigated extensively. Several algorithms aim to find close-to-optimal solution based on global information. Both [2] and [12] apply linear programming techniques to select the minimal set of active nodes for maintaining coverage. More sophisticated coverage model is used to address exposure-based coverage problems in [10][11]. The maximal breach path and maximal support path in a sensor network are computed using Voronoi diagram and Delaunay Triangulation techniques in [10]. The problem of finding the minimal exposure path is addressed in [11]. In [5], sensor deployment strategies were investigated to provide sufficient coverage for distributed detection. Provided scalability and fault-tolerance, localized algorithms are more suitable and robust for large-scale wireless sensor network that operate in dynamic environments. The protocol proposed in [14] depends on local geometric calculation of sponsored sectors to preserve sensing coverage. None of the above coverage maintenance protocols addresses the problem of maintaining network connectivity. On the other hand, several other protocols (e.g., ASCENT [1], SPAN [3], AFEC [16], and GAF [17]) aim to maintain network connectivity, but do not guarantee sensing coverage. Unfortunately, satisfying only coverage or connectivity alone is not sufficient for a sensor network to provide sufficient service. Without sufficient sensing coverage, the network cannot monitor the environment with sufficient accuracy or may even suffer from “sensing voids” — locations where no sensing can occur. Without sufficient connectivity, nodes may not be able to coordinate effectively or transmit data back to base stations. The combination of coverage and connectivity is a special requirement introduced by sensor networks that integrate multi-hop wireless communication and sensing capabilities into a single platform. In contrast, traditional mobile ad hoc networks comprised of laptops only need to maintain network connectivity.

A second limitation of the aforementioned coverage protocols (except for the global algorithm in [2]) is that they can only provide a fixed degree of coverage. They cannot dynamically reconfigure to meet different coverage requirements of applications. Finally, while the PEAS [18] protocol was designed to address both coverage and connectivity in a configurable fashion, it does not provide analytical guarantees on the degree of coverage and connectivity, which are required by many critical sensor network applications (e.g., surveillance and structural monitoring).

The main contributions of this paper are as follows. We provide a geometric analysis of the fundamental relationship between coverage and connectivity. This analysis gives underlying insights for treating coverage and connectivity in a unified framework. This is in sharp contrast to several existing works that address the two problems in isolation. We present a Coverage Configuration Protocol (CCP) that can dynamically configure the network to provide different feasible degrees of coverage requested by applications. This flexibility allows the network to self-configure for a wide range of applications and environments with diverse or changing coverage requirements. We integrate CCP with a representative connectivity maintenance protocol (SPAN [3]) to provide both coverage and connectivity guarantees.

In the rest of this paper, we first formulate the problem of coverage and connectivity in Section 2. The relationship between coverage and connectivity is analyzed in Section 3. We then present the design and analysis of CCP in Section 4 and propose a simple solution to configure both coverage and connectivity based on CCP in Section 5. Extensive simulation results are presented in Section 6. We offer conclusions in Section 7.

2. PROBLEM FORMULATION

Several coverage models [10][11][12] have been proposed for different application scenarios. In this paper, we assume a point $p$ is covered (monitored) by a node $v$ if their Euclidian distance is less than the sensing range of $v$, $R_s$, i.e., $|pv| < R_s$. We define the sensing circle $C(v)$ of node $v$ as the boundary of $v$’s coverage region. We assume that any point $p$ on the sensing circle $C(v)$ (i.e., $|pv| = R_s$) is not covered by $v$. Although this definition has an insignificant practical impact, it simplifies our geometric analysis in following sections. Based on the above coverage model, we define a convex region $A$ (that contains at least one sensing circle) as having a coverage degree of $K$ (i.e., being $K$-covered) if every location inside $A$ is covered by at least $K$ nodes. Practically speaking, a network with a higher degree of coverage can achieve higher sensing accuracy and be more robust against sensing failures. The coverage configuration problem can be formulated as follows. Given a convex coverage region $A$, and a coverage degree $K$ specified by the application (either before or after deployment), we must maximize the number of sleeping nodes under the constraint that the remaining nodes must guarantee $A$ is $K$-covered.

Despite its simplicity, this coverage model is applicable in a number of applications. For example, it fits well with the decision fusion approach to distributed detection (e.g., Bayesian Detection and Neyman-Pearson Test) [15], where each sensor sends 1 to a fusion node if it detects a target and sends 0 otherwise. The fused detection decision is based on the binary decisions of multiple
sensors. The goal of distributed detection problem is to maximize the detection probability under the constraint that the false alarm rate is less than a required threshold \( P_f \). The solution to this constrained optimization problem at each sensor follows the form of Likelihood Ratio Test (LRT), i.e., if the ratio of the conditional probabilities of the sensor reading is larger than a LRT threshold \( \lambda \) decided by \( P_f \), the sensor will report 1, otherwise report 0 to fusion center. Under some assumptions on the signal decay model and statistical distributions of event signals and background noise, the sensing range of a sensor can be derived from the LRT threshold \( \lambda \), i.e., the detection probability of the events within the sensing range is maximized while the false alarm probability is less than the required threshold \( P_f \). It should be noted that the term “sensing range” does not imply a hard boundary between the area where an event is always detected and the area where an event is never detected. Instead, the sensing range is often defined by the threshold of false alarm rate (probability). Therefore, the statistical nature of sensor network applications and the environments can be incorporated in the definition of sensing range. Exploring more sophisticated coverage models and corresponding applications is left as our future work.

In addition, we assume that any two nodes \( u \) and \( v \) can directly communicate with each other if their Euclidean distance is less than a communication range \( R_c \), i.e., \( |uv| < R_c \). Given a coverage region \( A \) and a sensor coverage degree \( K_s \), the goal of an integrated coverage and connectivity configuration is maximizing the number of nodes that are scheduled to sleep under the constraints that the remaining nodes must guarantee: 1) \( A \) is at least \( K_s \)-covered, and 2) all active nodes are connected.

### 3. RELATIONSHIP BETWEEN COVERAGE AND CONNECTIVITY

The first part of our investigation focuses on understanding the relationship between coverage and connectivity. Does coverage imply connectivity or vice versa so that a sensor network only needs to be configured to satisfy the stronger of the two requirements? In this section, we first derive a sufficient condition when coverage implies connectivity in a network. We then quantify the relationship between the degree of coverage and connectivity. The analysis presented in this section will serve as the foundation for an integrated solution to the problem of integrated coverage and connectivity configuration.

#### 3.1 Sufficient Condition for 1-Coverage to Imply Connectivity

In this subsection, we analyze the relationship between 1-coverage and connectivity in a network. We note that connectivity only requires that the location of any active node be within the communication range of one or more active nodes such that all active nodes can form a connected communication backbone, while coverage requires all locations in the coverage region be within the sensing range of at least one active node.

Intuitively, the relationship between connectivity and coverage depends on the ratio of the communication range to the sensing range. However, it is easily seen that a connected network may not guarantee its coverage regardless of the ranges. This is because coverage is concerned with whether any location is uncovered while connectivity only requires all locations of active nodes are connected. Hence we focus on analyzing the condition for a covered network to guarantee connectivity in the rest of this section.

Define the graph \( G(V,E) \) to be the communication graph of a set of sensors, where each sensor in the set is represented by a node in \( V \), and for any node \( x \) and \( y \) in \( V \), the edge \((x,y) \in E\) if and only if the Euclidean distance between \( x \) and \( y \), \(|xy|<R_c\). Node \( v \) and \( u \) are connected in \( G(V,E) \) if and only if a network path consisting of consecutive edges in \( E \) exists between node \( u \) and \( v \).

**Theorem 1:** For a set of sensors that at least 1-cover a convex region \( A \), the communication graph is connected if \( R_c \geq 2R_s \).

**Proof:** For any two nodes \( u \) and \( v \) in region \( A \), let \( P_{uv} \) be the line segment joining them. Since region \( A \) is convex, \( P_{uv} \) remains entirely within \( A \). Hence any point on \( P_{uv} \) is at least 1-covered. Each point \( p \) on \( P_{uv} \) has a set of one or more closest sensors equidistant from \( p \). A finite sequence \( S_{uv} = s_1..s_n \) of closest sensor sets can be constructed for contiguous segments 1..n of \( P_{uv} \), where a segment is defined by all points within it having the same set of closest sensors. \( S_{uv} \) starts with \( s_1 = \{u\} \) and ends with \( s_n = \{v\} \), with intervening sets possibly containing other sensors.

The distance from each point on the line segment \( P_{uv} \) to its closest sensor(s) is always less than \( R_s \), as otherwise the path would go through regions that are not sensor-covered. Furthermore, if there were any two sensors \( x \) and \( y \) in any consecutive sets \( s_i \) and \( s_{i+1} \) in \( S_{uv} \), \( x \in s_i \) and \( y \in s_{i+1} \), such that \(|xy| \geq 2R_s\), then the point \( p \) at the intersection of \( P_{uv} \) with the sensing circle of \( x \) is exactly \( R_s \) from \( x \) and not covered by \( x \) from the definition of sensing circle in Section 2 and according to the triangle inequality is at least \( R_c \) from \( y \). However, since that point would then have \( x \) as one of its closest sensors, it would be at least \( R_s \) from any sensor and thus would not be sensor-covered. Therefore, the distance between every pair of sensors in consecutive sets in \( S_{uv} \) is less than \( 2R_s \), and is thus less than \( R_c \), so an edge exists between them in the communication graph. Because each set in \( S_{uv} \) contains at least one sensor, we can thus construct a communication path from \( u \) to \( v \) through each combination of node choices in the sets in \( S_{uv} \), i.e., the communication graph of sensors in region \( A \) is connected. \( \square \)

Therefore, Theorem 1 establishes a sufficient condition for a 1-covered network to guarantee one-connectivity. Under the condition that \( R_c \geq 2R_s \), a sensor network only needs to be configured to guarantee coverage in order to satisfy both coverage and connectivity.

#### 3.2 Relationship between the Degree of Coverage and Connectivity

The previous section argues that if a region is sensor covered, then the sensors covering that region are connected as long as their communication range is no less than twice the sensing range. If we maintain the condition of \( R_c \geq 2R_s \), we can quantify the relationship between the degree of coverage and connectivity. This result is important for applications that require degrees of coverage or connectivity greater than one.

We define boundary sensor as a sensor whose sensing circle intersects with the boundary of the convex sensor deployment region \( A \). Clearly all boundary sensors are located within \( R_s \) distance to the boundary of \( A \). All the other sensors in region \( A \) are interior sensors.
Lemma 1: For a $K_s$-covered convex region $A$, it is possible to disconnect a boundary node from the rest of the nodes in the communication graph by removing $K_s$ sensors if $R_c \geq 2R_s$.

Proof: Consider the scenario illustrated by Figure 1: a sensor $u$ is located at a corner (point $q$) of the rectangular sensor deployment region $A$ that is $K_s$-covered. Suppose point $p$ is on the sensing circle of sensor $u$ such that $pq$ has a $45^\circ$ angle with the horizontal boundary of $A$.

Figure 1. Removing $K_s$ nodes disconnects a covered network

Suppose $K_s$ coinciding sensors are located at point $p$. Clearly, these $K_s$ sensors can $K_s$-cover the quarter circle of sensor $u$. And we assume there are no other sensors whose sensing circles intersect with sensing circle of $u$. Then removing these $K_s$ coinciding sensors will create an uncovered region (i.e., a sensing void) surrounding sensor $u$. Furthermore, when $R_c$ is equal to $2R_s$, there is no sensor within the communication range of sensor $u$ after the removal of these $K_s$ sensors. i.e., the communication graph is disconnected. □

Theorem 2: A set of nodes that $K_s$-cover a convex region $A$ forms a $K_s$ connected communication graph if $R_c \geq 2R_s$.

Proof: Disconnecting the communication graph $G$ of a set of sensors creates (at least) 3 disjoint sets of nodes, the set of nodes $W$ that is removed, and two sets of nodes $V_1$ and $V_2$, such that there are no edges from any node in $V_1$ to any node in $V_2$ in $G$. By Theorem 1, if it is possible to draw a continuous path between two nodes so that every point on the path is sensor-covered, then there exists a communication path between those two nodes. Therefore, to disconnect the graph it is necessary to create a sensing void, so that it is impossible to draw a continuous covered path connecting a node in $V_1$ to a node in $V_2$. That is, as illustrated in Figure 2, the nodes of $V_1$ may all lie in region $S$, the nodes in $V_2$ may all lie in region $Q$, and a set of nodes $W$ must be removed to make a region $T$ that is 0-covered. The nodes that are removed may actually lie in the region labeled $S$ or $Q$, but their removal leaves the 0-covered region labeled $T$.

Figure 2. A disconnected network

To create a sensing void in an originally $K_s$-covered region $A$, it is clearly necessary to remove at least $K_s$ sensors. Thus the network connectivity is at least $K_s$. By Lemma 1, removing $K_s$ sensors could disconnect the communication graph. So the tight lower bound on the connectivity of communication graph is $K_s$. □

Intuitively, the connectivity of the boundary sensors dominates the overall connectivity of the communication graph. However, in a large-scale sensor network, the interior sensors normally route more traffic and higher connectivity is needed for interior sensor to maintain the required throughput. We define interior connectivity as the number of sensors (either interior or boundary) that must be removed to disconnect any two interior sensors in the communication graph of the sensors.

Theorem 3: For a set of sensors that $K_s$-cover a convex region $A$, the interior connectivity is $2K_s$ if $R_c \geq 2R_s$.

Proof: Suppose $u$ and $v$ are two interior nodes and the removal of a set of nodes $W$ disconnects node $u$ and node $v$. In order for nodes $v$ and $u$ to be disconnected, there must be a “void” region that separates node $v$ from node $u$. There are two cases, either this void is completely contained within the sensor deployment region, or the void merge with the boundary of the region.

Case 1: As illustrated in Figure 3, the void does not merge with the boundary. We will prove one must remove at least $2K_s+1$ sensors in this case to create such a void. We prove by contradiction. Suppose $|W| < 2K_s+1$. In this case, the void must completely surround a set of nodes including node $v$. Since node $v$ remains active, the sensing void must be at a distance at least $R_c$ from $v$. Draw a line from $v$ through a sensor node $j$ in $W$. Let's define line $vj$ to be the direction we refer to as ‘vertical’. Now, there are at most $2K_s$-1 remaining sensors (except sensor $j$) in $W$ which are either on the line $vj$ or to the left or the right of line $vj$. By the pigeonhole principle, there must be one side that has less than $K_s$ nodes from the set $W$. Let's define that to be the left side. Draw the line straight left from $v$ until it intersects the void region, and call this point $p$ (note that $p$ is covered by zero sensors.) Point $p$ is at least $R_c$ from node $v$, and is at least $R_c$ from any point on or to the right of the vertical line. However, there are at most $K_s$-1 nodes in the set $W$ that are to the left of the line. This contradicts the assertion that $p$ was originally $K_s$ covered and the removal of the nodes of $W$ leaves it 0-covered. Thus $|W|$ is at least $2K_s+1$.

Figure 3. Case 1: The void does not merge with boundary

Figure 4. Case 2: The void merges with boundary

Case 2: The void merges with the boundary of region $A$, as illustrated in Figure 4. In this case, the removal of a set of nodes $W$ creates a void which separates the nodes $v$ and $u$, and this void merges with the boundary of the region $A$ that is being sensed. Since $v$ is an interior node, all the points within a radius $R_c$ from $v$...
are inside region A, and the same holds true for u. Furthermore, since the region A is convex, the line connecting any point v' within Rs from v and any point u' within Rs from u are inside the region A and must be intersected by the void, otherwise there will exist a continuous path (vv'uu') from v to u, which remains entirely within sensor covered region and defines a network path in the communication graph (from Theorem 1). Thus the minimum width of the void that separates u from v is at least 2Rs. Consider any two points in the void that are a distance of 2Rs apart. No sensor can simultaneously cover both points. This implies that at least 2Rs sensors were removed in the K_s-covered region A to create the void. We prove this bound is tight by the following example. Suppose the K_s-covered region A is a rectangle A1A2A3A4 with width 2R_s+r (0 < r < R_s). Two points x and y are located at perpendicular bisector of A1A2 and have distance (R_s+r)/2 < R_s with A1A2 and A3A4 respectively, as shown in Figure 4. Suppose there are K_s sensors (shown as dotted circles) located at point x and y respectively. W is composed of these 2K_s sensors. We assume the sensors (not shown in the figure) whose sensing circles intersect the 2K_s sensors in W are far enough from point x and y such that the void created by the removal of W intersects both A1A2 and A3A4. It is clear that the void disconnects the nodes on left side from the nodes on right side in communication graph.

From the proof of case 1 and case 2, for a set of sensors that K_s-cover a convex region, we have shown that the tight lower bound on the interior connectivity is 2K_s. □

We should note that the interior connectivity defined in this section is different from the connectivity of the communication sub-graph composed of solo interior nodes. This is because an interior node could connect to another interior node via boundary nodes and the communication sub-graph composed of solo interior nodes could be disconnected if all boundary nodes are removed, as illustrated by Figure 4.

From the Theorems 2 and 3, we can draw the conclusion that the boundary nodes that are located within Rs distance to the boundary of the coverage region are K_s-connected; to the rest of the network, the interior connectivity is 2K_s.

4. COVERAGE AND CONNECTIVITY CONFIGURATION WHEN R_c ≥ 2R_s

Based on Theorems 1, 2 and 3, the integrated coverage and connectivity configuration problem can be handled by a coverage configuration protocol if R_c ≥ 2R_s. In this section, we present a new coverage configuration protocol called CCP that uses this principle. CCP has several key benefits. 1) CCP can configure a network to the specific coverage degree requested by the application. 2) It is a decentralized protocol that only depends on local states of sensing neighbors. This allows CCP to scale effectively in large sensor networks in which nodes can fail at run-time. It also allows applications to change its coverage degree at run-time without incurring high communication overhead. 3) Our geometric analysis has proven that CCP can provide guaranteed degrees of coverage.

4.1 K_s-Coverage Eligibility Algorithm

Each node executes an eligibility algorithm to determine whether it is necessary to become active. Given a requested coverage degree K_s, a node v is ineligible if every location within its coverage range is already K_s-covered by other active nodes in its neighborhood. For example, assume the nodes covering the shaded circles in Figure 5 are active, the node with the bold sensing circle is ineligible for K_s=1, but eligible for K_s > 1. Before presenting the eligibility algorithm, we define the following notation.

- The sensing region of node v is the region inside its sensing circle, i.e., a point p is in v’s sensing region if and only if |pv| < R_v.
- A point p∈A is called an intersection point between nodes u and v, i.e., p∈u∩v, if p is an intersection point of the sensing circles of u and v.
- A point p on the boundary of the coverage region A is called an interior point between nodes v and A, i.e., p∈v∩A if |pv|=R_v.

Figure 5. An example of K_s-eligibility

Theorem 4: A convex region A is K_s-covered by a set of sensors S if 1) there exist in region A intersection points between sensors or between sensors and A’s boundary; 2) all intersection points between any sensors are at least K_s-covered; and 3) all intersection points between any sensor and A’s boundary are at least K_s-covered.

Proof: We prove by contradiction. Let p be the point that has the lowest coverage degree k in region A and k < K_s. Furthermore, suppose there is no intersection point in A which is covered to a degree less than K_s. The set of sensing circles partition A into a collection of coverage patches, each of them is bounded by arcs of sensing circles and/or the boundary of A, and all points in each coverage patch have the same coverage degree. Suppose point p is located in coverage patch S. First we prove that the interior arc of any sensing circle cannot serve as the boundary of S. We prove by contradiction. Assume there exists an interior arc (of sensing circle C(u)) serving as the boundary of S, crossing this arc (i.e. leaving the coverage region of sensor u) would reach an area that is lower covered than point p. This contradicts with the assumption that point p has the lowest coverage degree in region A. Now we consider the following two cases:

Figure 6. A coverage patch bounded by arcs of sensing circles
1) The point p lies in a coverage region S whose boundary is only composed of exterior arcs of a collection of sensing circles (as Figure 6 illustrates). Furthermore, since the sensing circles themselves are outside the sensing range of the nodes that define them, the entire boundary of this coverage patch, including the intersection points of the sensing circles defining the boundary, has the same coverage degree as point p. This contradicts the assertion that p is covered to a degree less than Ks and all intersection points have coverage degree at least Ks.

2) The point p lies in a coverage region S that is bounded by the exterior arcs of a collection of sensing circles and the boundary of region A. As shown in Figure 7, point p is in a region bounded by the exterior arcs of sensor u, v, w, x and the boundary of region A. Similarly as case 1), the entire boundary of this coverage patch, including the intersection points of sensors u, v, w, x and boundary of A, has the same coverage degree as point p. This contradicts the assertion that p is covered to a degree less than Ks and all intersection points have coverage degree at least Ks.

Clearly the point p can’t lie in a coverage patch that is bounded solely by the boundary of region A. Otherwise the region A has the same coverage as point p. This contradicts with the assumption that the region A is Ks covered. From the above discussion, the point p with lower coverage degree than Ks doesn’t exist. Thus the region A is Ks covered. □

Theorem 4 allows us to transform the problem of determining the coverage degree of a region to the simpler problem of determining the coverage degrees of all the intersection points in the same region. A sensor is ineligible for turning active if all the intersection points inside its sensing circle are at least Ks-covered. To find all the intersection points inside its sensing circle, a sensor v needs to consider all the sensors in its sensing neighbor set, SN(v). SN(v) includes all the active nodes that are within a distance of twice of the sensing range to v, i.e., SN(v) = \{active node u | |uv| ≤ 2Rs and u≠v\}. If there is no intersection point inside the sensing circle of sensor v, v is ineligible when there are Ks or more sensors that are located at sensor v’s position.

The resulting coverage eligibility algorithm is shown in Figure 8. The computational complexity for the eligibility algorithm is O(N^2) where N is the number of nodes in the sensing neighbor set. The eligibility algorithm requires the information about locations of all sensing neighbors. CCP maintains a table of known sensing neighbors based on the beacons (HELLO messages) that it receives from its communication neighbors. When Rs ≥ 2Rs, the HELLO message from each node only needs to include its own location. When Rs < 2Rs, however, a node may not be aware of all sensing neighbors through such HELLO messages. Since some sensing neighbors may be “hidden” from a node, it might activate itself to cover a perceived sensing void that is actually covered by its hidden sensing neighbors. Thus the number of active nodes would be higher than necessary in this case. To address this limitation, there must be some mechanism for a node to advertise its existence to the neighborhood of 2Rs range.

There are two approaches to make each node aware of its multi-hop neighbors. One is to broadcast HELLO messages in multiple hops by setting the TTL of each HELLO message. The other is to let each node include the locations of all known multi-hop neighbors in its HELLO messages. Specifically, each node may broadcast the locations and status of all active nodes within [2Rs/Rc] hops. The second approach reduces the number of broadcasts and is adopted by CCP (this approach is also used by SPAN to maintain two-hop neighborhood tables). We should note that, in a network with random topology, such HELLO messages still can’t guarantee the discovery of all nodes within a distance of 2Rs. Since including multi-hop neighbors in the HELLO messages introduce much higher communication overhead compared to a one-hop approach in a dense network, there is a tradeoff between the beacon overhead and the number of active nodes maintained by CCP. We investigate this trade-off through experiments in Section 6.2.

We note that a special case (when coverage degree Ks = 1) of Theorem 4 was stated in [8], but it did not provide any proof. Moreover, Theorem 4 presents a more general case that applies to any degree of coverage. This general case is important because flexible coverage configuration is a focus of this paper.

4.2 The State Transition of CCP

In CCP, each node determines its eligibility using the Ks-coverage eligibility algorithm based on the information about its sensing neighbors, and may switch state dynamically when its eligibility changes. A node can be in one of three states: SLEEP, ACTIVE, and LISTEN. In the SLEEP state, the node sleeps to conserve energy. In the ACTIVE state, the node actively senses the environment and communicates with other sensors. Each node periodically enters the LISTEN state to collect HELLO messages from its neighbors and reevaluates its eligibility to determine its eligibility algorithm based on the information about its sensing neighbors in its HELLO messages. Specifically, each node may broadcast the locations and status of all active nodes within [2Rs/Rc] hops. The second approach reduces the number of broadcasts and is adopted by CCP (this approach is also used by SPAN to maintain two-hop neighborhood tables). We should note that, in a network with random topology, such HELLO messages still can’t guarantee the discovery of all nodes within a distance of 2Rs. Since including multi-hop neighbors in the HELLO messages introduce much higher communication overhead compared to a one-hop approach in a dense network, there is a tradeoff between the beacon overhead and the number of active nodes maintained by CCP. We investigate this trade-off through experiments in Section 6.2.

We note that a special case (when coverage degree Ks = 1) of Theorem 4 was stated in [8], but it did not provide any proof. Moreover, Theorem 4 presents a more general case that applies to any degree of coverage. This general case is important because flexible coverage configuration is a focus of this paper.

4.2 The State Transition of CCP

In CCP, each node determines its eligibility using the Ks-coverage eligibility algorithm based on the information about its sensing neighbors, and may switch state dynamically when its eligibility changes. A node can be in one of three states: SLEEP, ACTIVE, and LISTEN. In the SLEEP state, the node sleeps to conserve energy. In the ACTIVE state, the node actively senses the environment and communicates with other sensors. Each node periodically enters the LISTEN state to collect HELLO messages from its neighbors and reevaluates its eligibility to determine its eligibility algorithm based on the information about its sensing neighbors in its HELLO messages. Specifically, each node may broadcast the locations and status of all active nodes within [2Rs/Rc] hops. The second approach reduces the number of broadcasts and is adopted by CCP (this approach is also used by SPAN to maintain two-hop neighborhood tables). We should note that, in a network with random topology, such HELLO messages still can’t guarantee the discovery of all nodes within a distance of 2Rs. Since including multi-hop neighbors in the HELLO messages introduce much higher communication overhead compared to a one-hop approach in a dense network, there is a tradeoff between the beacon overhead and the number of active nodes maintained by CCP. We investigate this trade-off through experiments in Section 6.2.

We note that a special case (when coverage degree Ks = 1) of Theorem 4 was stated in [8], but it did not provide any proof. Moreover, Theorem 4 presents a more general case that applies to any degree of coverage. This general case is important because flexible coverage configuration is a focus of this paper.
When the ratio of the communication range to the sensing range is less than 2, the active nodes picked by CCP eligibility rule guarantee that the region is covered to the required degree. However, these active nodes might not communicate with each other. In this case, the eligibility rule SPAN will activate extra nodes so that every node can reach a active node within its communication range.

In SPAN, a HELLO message includes the node’s location coordinates and the IDs of neighboring coordinators. Thus a node can know the existences of coordinators in two-hop neighborhood. We modified the structure of the SPAN HELLO message to include the coordinates of each neighboring coordinator. Thus, a node can maintain a neighborhood table that includes the locations of all two-hop neighboring coordinators from the HELLO messages. As discussed in Section 4.1, the information about the locations of two-hop active neighbors can reduce the number of active nodes under CCP when \( R_c/R_s < 2 \). We examine the effect of using 2-hop information in Section 6.
6. EXPERIMENTATION

In this section, we present the results of three sets of simulation experiments. Experiment I tests CCP’s capability to provide different degrees of coverage. Experiment II evaluates CCP and CCP+SPAN in terms of both coverage and connectivity on NS-2. Experiment III tests the system lifetime of CCP+SPAN protocol.

6.1 Experiment I: Coverage Configuration

Experiment I is performed on the Coverage Simulator (CS) provided by the authors of [14]. Although CS is a simple simulation environment that assumes perfect wireless communication and doesn’t account for communication overhead, this light-weight simulator allows us to evaluate CCP’s eligibility algorithm over a wide range of network settings. It has also been shown to provide similar coverage performance results to NS-2 when evaluating the coverage preservation protocol developed by University of Ottawa [14].

Experiment I compares the performance of CCP to the Ottawa protocol described in [14]. Similar to CCP, the Ottawa protocol is a decentralized protocol designed to preserve coverage while turning off redundant nodes to conserve energy in a sensor network. Simulation results reported in [14] also demonstrated that this protocol can provide better coverage than the PEAS protocol [18], which is designed to control density rather than coverage. The Ottawa protocol and CCP utilize different eligibility rules. The main advantage of CCP over the Ottawa protocol lies in its ability to configure the network to the specific coverage degree requested by an application, while the Ottawa protocol does not support different coverage configurations. In addition, our experimental results show that even when only 1-coverage is required, CCP results in a smaller number of active nodes and hence leads to more energy conservation than the Ottawa protocol. All the results in this section are based on five runs with different random network topologies. The region used for testing in Experiment I is 50m×50m if not specified otherwise, and the sensing range is 10m for all sensor nodes.

![Figure 9. Average Coverage Degree](image)

**Figure 9. Average Coverage Degree**

6.1.1 The Efficiency of CCP

To measure coverage, we divide the entire sensing region into 1m×1m patches. The coverage degree of a patch is approximated by measuring the number of active nodes that cover the center of the patch. Figure 9 compares the average coverage degree of all patches for CCP and the Ottawa protocol. The requested coverage degree is $K_s = 1$ for CCP. The average coverage degree of CCP remains around 2 in all combinations of network size and numbers of nodes. In contrast, the Ottawa protocol results in an average coverage degree between 4 and 6, and increases with the number of nodes. Figure 10 shows the distribution of coverage degrees with 100 nodes. Each data point represents the percentage of patches with a coverage degree no lower than that specific level. The data set “Original” represents the coverage percentage of the original network. While both protocols achieve full coverage as required, the number of nodes that has unnecessarily high coverage degrees is significantly smaller when CCP is used. For example, while CCP results in only 1% of nodes being 4-covered, over 80% of the patches are at least 4-covered with the Ottawa protocol. Figure 11 shows the number of active nodes under the Ottawa protocol and CCP (with different requested coverage degrees).

![Figure 10. Distribution of Coverage Degree](image)

**Figure 10. Distribution of Coverage Degree**

The number of active nodes used by CCP (when $K_s = 1$) is less than half of the number of nodes activated by the Ottawa protocol when the number of deployed nodes is 100. When the number of deployed nodes reaches 900, the number of active nodes for CCP is less than 25% of that for the Ottawa protocol. The number of active nodes used by the Ottawa protocol increases when the number of deployed nodes increases, while CCP maintains the same number of active nodes. This is because the eligibility rule in CCP makes decisions based on knowledge about the nodes within twice the sensing range, while the eligibility algorithm in the Ottawa protocol can only utilize the information nodes within the sensing range. In addition, the Ottawa protocol requires that all nodes close to the boundary of the region remain active, which can lead to a large number of additional active nodes when a large number of nodes are deployed. In contrast, CCP is able to turn off redundant nodes close to the network boundary. In summary, the above experiments show that our eligibility rule can preserve coverage with fewer active nodes. That in turn will consume less power, and thus extend the lifetime of the network.

6.1.2 The Configurability of CCP

In this subsection, we evaluate CCP’s ability to configure the network to achieve requested coverage degrees. In Figure 11, we plot resulting coverage degrees under different requested coverage degrees and different numbers of deployed nodes (500, 700, and 900). The line labeled “Min-500, 700, 900” represents the mini-
mum resulting coverage degree among all patches for different requested coverage degrees.

![Figure 11. Comparison of Active Node Number](image)

Figure 11. Comparison of Active Node Number

The minimum coverage degree remains close to the requested coverage degree. This result demonstrates that CCP can guarantee requested degrees of coverage without introducing unnecessary redundancy. Figure 12 also shows that the ratio of average coverage degree to the minimum coverage degree decreases as the requested coverage degree increases. Finally, as shown in Figure 12, the number of active nodes of CCP is proportional to the degree of coverage. This allows CCP to scale to any feasible degree of coverage requested by the application.

![Figure 12. Coverage Degree vs. Required Coverage Degree](image)

Figure 12. Coverage Degree vs. Required Coverage Degree

6.2 Experiment II: Coverage and Communication Performance

Experiment I has shown that CCP can provide configurable coverage by keeping a small number of nodes active. In this subsection, we evaluate the capability of several protocols in terms of providing integrated coverage and connectivity configuration in NS-2. The following protocols are compared:

- **SPAN**: obtained from MIT (http://www.pdos.lcs.mit.edu/span/).
- **CCP**: implemented by replacing the SPAN’s coordinator eligibility rule with CCP’s.
- **SPAN+CCP**: implemented by combining the eligibility rules of SPAN and CCP as described in Section 5.
- **CCP-2Hop**: implemented by adding the locations of a node’s neighboring coordinators in its HELLO message (as described in Section 4.1).
- **SPAN+CCP-2Hop**: SPAN+CCP with extended HELLO messages as in CCP-2Hop.

We simulated all protocols in NS-2 with the CMU wireless extensions [4]. All protocols were run on top of the 802.11 MAC layer with power saving support and improvements from [3]. In a 400×400m² coverage region, 160 nodes are randomly distributed in the field initially and remain stationary once deployed. Similar to [3], to ensure a data packet must go through multiple hops before reaching the destination, ten sources and ten sinks are randomly placed in opposite sides of the region. Each of these nodes sends a CBR flow to destination node located on the other side of the region, and each CBR flow sends 128 byte packets with 3Kbps rate. The routing protocol we used is the greedy geographic forwarding algorithm described in [3]. Nodes in our simulations use radios with a 2 Mbps bandwidth and a sensing range of 50 m. We used TwoRayGround radio propagation model in all NS-2 simulations. To measure the performance of different protocols under different ratios of communication range/sensing range, we varied the communication range by setting appropriate values of the receiving threshold in the network interface. All experimental results presented in this section are averages of five runs on different randomly chosen scenarios. The requested coverage degree $K_s = 1$ in all the experiments in this section.

![Figure 13. Network Topology and Coverage in a Typical Run (Rc/Rs = 1.5)](image)

Figure 13. Network Topology and Coverage in a Typical Run ($R_c/R_s = 1.5$)

(a) SPAN  (b) CCP  (c) SPAN-CCP-2Hop

Figure 13(a-c) show the network topology and coverage produced by SPAN, CCP, and SPAN-CCP-2Hop for $R_c/R_s = 1.5$ after 300 seconds of simulation time in 3 typical runs. The medium-sized
dots represent source and sink nodes located at two opposite sides of the network; the large dots represent active nodes; and the small dots are inactive nodes. The sensing ranges of active nodes are represented by circles. As expected, SPAN leaves some areas (close to the boundary) of the region uncovered, even though it maintains network connectivity. Although CCP maintains both connectivity and coverage, its topology has large voids in the network causing low communication throughput. In contrast, SPAN-CCP-2Hop maintains both coverage and satisfactory topology. This example illustrates the need for integrating CCP and SPAN when \( R_c/R_s < 2 \).

![Figure 14. Coverage Percentage vs. \( R_c/R_s \)](image1)

We now present detailed performance results. The goal of our protocols is to maintain both connectivity and coverage while reducing the number of active nodes. Figure 14 shows the coverage percentage of five protocols on a sensor network. The sensing range is 50m and the communication range varies from 50m to 125m. Similar to Experiment I, we divide the field into 1m \( \times \) 1m patches. A patch is covered if the center of the patch is inside the sensing circle of an active node.

The percentage of coverage is computed as the ratio of the number of covered patches to the total number of patches 300 seconds after the simulation starts. From Figure 14, we can see that CCP, CCP-2Hop, SPAN+CCP, SPAN+CCP-2Hop can maintain coverage percentage close to 100%, for all \( R_c/R_s \) ratios. Specifically, a majority of the coverage numbers is 100% and all remaining numbers are above 99.99%. After a further investigation, we found this is because in some rounds of experiments, the 160 randomly distributed sensors of the original network don’t provide 100% coverage to the deployment region. The overall results show that CCP can effectively maintain coverage. The coverage percentage provided by SPAN increases when the \( R_c/R_s \) ratio drops and reaches about 96% when \( R_c/R_s = 1 \). This is because when the radio radius drops, network connectivity decreases accordingly and SPAN selects more communication coordinators to maintain the communication capacity. Since SPAN does not consider coverage requirement at all, it fails to achieve full coverage in any of the tested configurations. When \( R_c/R_s \) increases, the coverage percentage drops quickly. This result shows that topology maintenance protocols alone are not able to maintain coverage.

Figure 15 shows the packet delivery ratios of all protocols over 300 seconds of simulation time. When \( R_c/R_s \) increases, all protocols deliver more packets, and 100% of the packets are delivered when \( R_c/R_s > 2 \). This is because when the communication range increases, the network becomes effectively denser and achieves higher connectivity. When \( R_c/R_s < 2 \), CCP-2Hop shows the worst delivery ratio since it only considers the coverage requirement, which does not guarantee connectivity under these conditions. CCP performs slightly better than CCP-2Hop since it produces more active nodes and thus higher connectivity due to the lack of location information about two-hop neighboring coordinators. All three remaining protocols perform similarly since SPAN provides better communication connectivity by activating more nodes. As illustrated in Figure 16, in order to provide capacity for both coverage and communication, SPAN+CCP-2Hop produces more active nodes than CCP-2Hop. In addition, although SPAN+CCP-2Hop introduces the overhead of sending location coordinates in HELLO messages, it performs as well as the original SPAN. When \( R_c \) is decreased to 50m, the network capacity becomes extremely low and no protocols (including the original SPAN) can deliver more than 50% of the packets. Exactly as predicted by our geometric analysis, CCP provides a 100% delivery ratio when \( R_c/R_s \geq 2 \) even though it does not explicitly maintain the network topology.

Figure 16 shows the number of active nodes of five protocols. When \( R_c/R_s \) increases, the effective network density increases accordingly, and all protocols activate fewer nodes. SPAN results in the least active nodes since it only maintains connectivity. SPAN+CCP and CCP perform similarly and result in the most active nodes. The 2-hop protocols outperform one-hop protocols when \( R_c/R_s < 2 \). This matches our expectation since in 2-hop protocols each node bases its decision on the knowledge of more active nodes in its sensing neighborhood. Also in this region, SPAN+CCP-2Hop keep more nodes active than CCP-2Hop because the active nodes selected by CCP eligibility rule might not communicate via one hop and SPAN thus activates extra nodes to provide better connectivity. Note Figure 15 shows that the extra nodes activated by SPAN+CCP-2Hop are necessary in order to maintain network connectivity.

---

* Note that this result does not conflict with Theorem 1 which gives a sufficient but unnecessary condition for connectivity.
We can see that the death of active nodes can cause slight fluctuations of the coverage percentage curves. However, the nodes failures do not affect the coverage percentage of original network until a majority of the nodes dies. This is because in original network with all nodes on, a large portion of the field has coverage degrees higher than 1. The system delivery ratios of SPAN+CCP drop below 90% at 650s with node density 200, at 740s with node density 250 and 730 seconds with node density 300 respectively.

6.3 Experiment III: System Life Time

This section shows that SPAN+CCP can extend the system lifetime significantly while maintaining both coverage and communication capacity. The metrics used in evaluating system lifetime are the coverage lifetime and the communication lifetime. The overall system lifetime is the continuous operational time of the system before either the coverage or delivery ratio drops below its specified threshold. For the experiments in this section we define both thresholds to be 90%. Figure 17 and Figure 18 show the system coverage and communication lifetime of SPAN+CCP and original network with all nodes on, respectively. In these experiments, each of 20 source and sink nodes starts with 5000 Joules of energy. Each source node sends a CBR traffic with 3Kbps rate. Three node deployment densities, 200, 250 and 300 are used for the remaining nodes in the experiments. With each density, the nodes are randomly distributed in a 400×400m² network field and each of them starts with an initial energy selected randomly within the range from 200 J to 300 J. The ratio of communication and sensing range is 2.5 in all experiments. We sampled the network coverage and delivery ratio from the simulation every 10 seconds. We follow the energy model of Cabletron Roamabout 802.11 DS High Rate network card operating at 2Mbps in base station mode, measured in [3]. The power consumption of Tx (transmit), Rx (receive), Idle and Sleeping modes are 1400mW, 1000mW, 830mW, 130mW respectively [3].

We can see from the Figure 17 that in the original network with all nodes on, the system coverage percentages drop below 90% at 270s with node density 200 and at 280s with densities 250 and 300, and keep dropping sharply thereafter because of a majority of nodes have run out of energy. Figure 18 illustrates similar results. The system delivery ratio drops below 90% after around 330 seconds, which is slightly longer than the system coverage lifetime.

On the other hand, as illustrated in Figure 17, SPAN+CCP keeps the coverage above 90% until 470s with node density 200, 530s with node density 250 and 560 seconds with node density 300.

In summary, the key results of our experiments are as follows:

- Coverage efficiency: CCP can provide one-coverage while keeping a significantly smaller number of active nodes than the Ottawa protocol. The number of active nodes remains steady with respect to network density for the same requested coverage degree.
• Coverage configuration: The CCP eligibility algorithm can effectively enforce different coverage degrees specified by the application. The number of active nodes remains proportional to the requested coverage degree.

• Integrated coverage and connectivity configuration: When $R_c/R_s \geq 2$, all protocols that employ CCP perform well in terms of packet delivery ratio, coverage, and the number of active nodes. When $R_c/R_s < 2$, CCP+SPAN-2Hop is the most effective protocol that provides both sufficient coverage and communication. SPAN cannot guarantee coverage under all tested conditions. These empirical results match our geometric analysis.

7. CONCLUSIONS AND FUTURE WORK

This paper explores the problem of energy conservation while maintaining both desired coverage and connectivity in wireless sensor networks. We provided a geometric analysis that 1) proves sensing coverage implies network connectivity when the sensing range is no more than half of the communication range; and 2) quantifies the relationship between the degree of coverage and connectivity. We developed the Coverage Configuration Protocol (CCP) that can achieve different degrees of coverage requested by applications. This flexibility allows the network to self-configure for a wide range of applications and (possibly dynamic) environments. We also integrate CCP with the SPAN to provide both coverage and connectivity guarantees when the sensing range is higher than half of the communication range. Simulation results demonstrate that CCP and CCP+SPAN+2Hop can effectively configure the network to achieve both requested coverage degrees and satisfactory communication capacity under different ratios of sensing/communication ranges as predicted by our geometric analysis. In the future, we will extend our solution to handle more sophisticated coverage models and connectivity configuration and develop adaptive coverage reconfiguration for energy-efficient distributed detection and tracking techniques.

8. ACKNOWLEDGEMENTS

We thank Nicolas D. Georganas and Dian Tian at University of Ottawa for providing the source code of Coverage Simulator, and Benjie Chen for making the SPAN simulation code available on the Web. We would also like to thank our shepherd Loren Clare and anonymous reviewers for their valuable suggestions.
